Arc-Induced Long Period Fiber Gratings in the Dispersion Turning Points

Celso Colaço, Paulo Caldas, Ignacio Del Villar, Rui Chibante, and Gaspar Rego

Abstract—We demonstrated the possibility to inscribe long-period fiber gratings (LPFGs) in a B/Ge co-doped fiber by using grating periods shorter than 150 μm. We have also arc-induced in the SMF 28 fiber a LPFG in the dispersion turning points by using a grating period of 197 μm. In previous works the shortest periods were respectively, of the order of 190 μm and 320 μm for the same fibers. To achieve such a considerable reduction in the grating periods which enables access to the higher order cladding modes (higher sensitivity), we have developed a high voltage power supply that allows for a constant and stable electric current ranging from 10.5 mA up to 21 mA. Computer simulations were used to identify the cladding mode resonances for each grating inscribed in the different fibers. The fabricated LPFGs were characterized as a function of the external refractive index from 1.33 up to 1.42 and an average refractive index sensitivity of 720 nm/RIU in the 1.33-1.41 range was obtained without further optimization, such as the use of etching or thin films deposition.

Index Terms— Long-period fiber grating, electric arc technique.

I. INTRODUCTION

LONG-PERIOD fiber gratings (LPFGs) are periodic structures inscribed in a fiber, with periods typically in the range of 100 μm to 1mm which couples light between the core mode and co-propagating cladding modes at specific resonance wavelengths. The gratings transmission spectra contains a series of attenuation bands centered at these discrete resonance wavelengths, each attenuation band corresponding to coupling of a different cladding mode. The gratings behave as selective filters, where the resonance wavelengths depend on the period of the LPFG and also on physical parameters, such as temperature, strain, external refractive index and bending radius. LPFGs can, therefore, be used as sensors of these parameters [1], [2].

Among the different techniques available to inscribe gratings, the electric arc technique is well-established and disseminated all over the world [3]. The interest of the scientific community results from it being a simple, versatile and low cost technique besides enabling the fabrication of gratings in any kind of fiber [4], [5]. Arc-induced gratings have considerable polarization dependent loss which limits their application in the optical communications field, such as is the case of the equalization of EDFAs gain spectrum [6]. On the other hand, they are thermally resistant and can be used as high temperature sensors [7]. It is well-know that higher sensitivity to the different physical parameters can be obtained if they are written in the dispersion turning points (DTP) [8], [9]. At these points, the slope of the phase matching curves, for each cladding mode resonance, reaches its maximum value. On the other hand, near the DTP the slope steeply increases and changes from positive to negative and, for each grating period, there are two resonance wavelengths for each cladding mode. This is due to the dependence on wavelength of the core and cladding effective refractive indices. For a particular grating period, the phase matching condition can be satisfied for more than one resonance wavelength (for the same cladding mode) since as the wavelength increases the effective refractive index of the cladding mode decreases faster than that of the core [8]. A higher sensitivity can be important to increase the temperature sensitivity of sensors to work in cryogenic environments [10] and also to develop high resolution refractometer sensors based on LPFGs in the DTP with thin films in the transition region [11]. During the past decade a lot of effort was focused on the understanding of the mechanisms of grating formation, types of modes excited and ways to increase reproducibility [12]- [18]. Being the grating formation associated to a thermal effect, it prevented the fabrication of arc-induced LPFGs in the DTP. Recently, Smietana et al. [19] demonstrated the inscription of LPFGs in the DTP by writing LPFGs in the B/Ge co-doped fiber with periods of the order of 190 μm and for which they have used more than 200 arc-discharges. Afterwards, Celso et al. [20] developed a new high voltage power supply to produce very confined arc discharges establishing a minimum period of 148 μm in a B/Ge co-doped fiber (LPFG attenuation bands of 4.5 dB after 142 arc discharges). It should be stressed that the quest for further reducing the grating period is very pertinent when one deals with the fabrication of LPFGs in few-mode
fibers (100-120 μm) [21] or LPFGs in the DTP written in photonic crystal fibers (100 μm) [22]. The same requirements apply to LPFGs assisted surface plasmon resonance (SPR) [23] where grating periods in the range of 110-120 μm are also needed. The requirement can only be relaxed in the case of long-range SPR where grating periods of about 200 μm may be used [24].

In this work we describe the whole process used to attain the DTP in the Corning SMF28 fiber and also in the Fibercore (PS 1250/1550) B/Ge co-doped fiber. We have also identified the cladding modes through computer simulations. Section II.A describes the experimental setup, comprising the new high voltage power supply, used to inscribe the gratings in three different fibers. The choice of the fabrication parameters depending on the fiber is also discussed in Section II. B. Section II.C describes the fabrication process of arc-induced gratings in the DTP and results of computer simulations to identify the cladding modes are presented. The influence of the external refractive index on the LPFGs transmission spectra is given in Section II.D.

II. EXPERIMENTAL RESULTS AND DISCUSSION

A. Experimental Setup

The experimental set-up used to fabricate the gratings is shown in Fig. 1. The whole process is computer controlled, being the mechanical arrangement used to control the fiber positioning/displacement established a decade ago [5]. In which concerns the electrical part, the power source used to feed the electrodes was supplied by the BICC AFS1300 fusion splicer [5]. As demonstrated in [17] the produced arc discharges were directional, due to the DC output, and had a large width, as expected for a fusion splicer machine even though the electrodes gap was only of 0.95 mm. Meanwhile, we have developed a new high voltage power source (also shown in Fig. 1) that allows for confined arc discharges. The dimensions of the arc can be further controlled by changing the distance between the electrodes (the shorter the electrodes gap the smaller is the arc width). The AC power source possesses a feedback loop that keeps a constant r.m.s. electric current, that is measured by a current sensing shunt resistor. The state of the electrodes can be monitored by using a digital oscilloscope. In Fig. 2 it can be seen a normal arc discharge and a discharge when the electrodes present some degradation. In the latter, to keep the same electric current (top Fig. 2 a-b), a higher voltage peak (bottom Fig. 2 b) for the arc ignition is required. That is, the electrodes oxidation demands for a higher voltage in order to establish the arc through air.

Gratings were inscribed in the SMF28 fiber and in two PS 1250/1550 B/Ge co-doped fibers from Fibercore (fiber #1: NA = 0.13; MFD = 9.6 μm; λ_{cut-off} = 1150 nm & fiber #2: NA = 0.14; MFD = 8.9 μm; λ_{cut-off} = 1238 nm) with grating periods ranging from 148 μm up to 540 μm (fabrication parameters: electric current of 11-18 mA; 200-700 ms arc duration; 2-5 g pulling weight; 20-400 arc discharges).

B. Optimization of the Fabrication Parameters

For this new high voltage power supply and for the sake of comparison with a well-known reference, we had to adjust the fabrication parameters in order to reproduce the spectrum of a grating inscribed in the SMF28 fiber with a period of 540 μm, obtained previously by using the BICC AFS1300 fusion splicer as a power source [17]. We obtained a similar spectra after 27 arc discharges using an electric current of 15 mA during 200 ms. To monitor the gratings spectra during their inscription we have used a white light source (WLS), from Ocean Optics HL-2000-HP, to illuminate the LPFGs and their transmission spectra were registered with an optical spectrum analyzer (OSA), from Yokogawa AQ6370C, with a resolution of 1 nm. The presented spectra are normalized to the spectrum of the WLS, taken 10 min after temperature stabilization. Fig. 3 shows the spectra of several gratings with a period of 400 μm written in the SMF28 fiber using different fabrication parameters (electrodes gap and external tension were set to 0.9 mm and 5.2 g, respectively). As can be seen, the increase of the electric current and arc duration lead to an increase of the
resonances coupling strength and also to a slight displacement towards longer wavelengths. The former is a well-known result but the latter is in contradiction with previous studies [25]. This may be due to the fact that in this setup, a smaller width of the arc discharge leads to a less effective stress relaxation of the cladding and, therefore, the change in the core refractive index prevails over that of the cladding. Then, we changed the fabrication parameters in order to inscribe gratings with shorter periods. To reach periods of about 200 μm we had to displace the fiber to a lower temperature region and higher temperature gradient, by down-shift the fiber relatively to the arc [16], [17]. This procedure reinforces coupling to asymmetric cladding modes as shown by simulations in Fig. 7a. Fig. 4 shows the spectra of gratings with different periods: 276 μm, 253 μm, 223 μm, 217 μm, 207 μm and 197 μm (the first two written with 260 arc discharges and the other with 400 arc discharges and an external tension of 2 g). The other fabrication parameters were respectively, 11 mA and 280 ms, 18.1 mA and 118 ms, 14 mA and 370 ms for the next two gratings, and 12.7 mA and 580 ms for the last two gratings. It should be stressed that we obtained strong gratings for periods above 350 μm while for periods around 200 μm only weak gratings (4 dB attenuation loss peaks) were attained.

Afterwards we inscribed gratings in the B/Ge co-doped fibers. We noted that for these fibers lower electric current values, arc duration and number of arc discharges were required in order to produce the gratings. In the case of the fiber #1, the fabrication parameters used were 13.8 mA, 308-320 ms and arc discharges ranging from 140 up to 170 (Fig. 5a). In the case of the fiber #2, the optimum fabrication parameters were 12.7 mA, 660-680 ms and 122 arc discharges (Fig. 5b). Then, for the sake of comparison, we have also used the same fabrication parameters to inscribe gratings in a short piece remaining from the first fiber (180 μm-LPFG in Fig. 5a). It should be noted that these fibers are two batches of the same Fibercore fiber but unfortunately they had different physical properties as described previously. Fig. 5 shows the spectra of...
several gratings written in both fibers, for which strong gratings were produced with only 122 arc discharges. However, the resonance wavelengths are different when the same grating periods are used. Consequently, the DTP is found for a different period, as we will see in the next subsection.

C. Gratings Fabrication in the Dispersion Turning Points

The fabrication parameters were optimized in order to be possible to write the gratings in the DTP. In particular we have decreased the electrodes gap (from 1.0 mm to 0.9 mm). A LPFG was inscribed in the SMF28 fiber with a period of 197 μm and its spectrum is shown in Fig. 6a. This LPFG is in the vicinity of the DTP since when surrounded by water the two resonances moves in opposite ways (see Fig. 10a). The fabrication parameters were: electric current of 12.7 mA, 600 ms arc duration, 2 g pulling weight and 400 arc discharges. It should be stressed that we are working in the limits of the electric arc technique since it was only possible to write a weak grating even after 400 arc discharges. Even so, this result is quite impressive since previously in this fiber the shortest period was larger than 300 μm [26]. Fig. 6b shows the arc-induced LPFG with the shortest grating period 148 μm. This grating was inscribed in fiber #1, from Fibercore, using the following fabrication parameters: electric current of 13.8 mA, 308 ms arc duration, 2 g pulling weight and 142 arc discharges. Since the mechanism of grating formation is different in this fiber [15] we believe that further optimization is still possible, in particular by changing the relative position between the fiber and the arc discharge. In any case we decreased the shortest period from about 190 μm [18] to less than 150 μm and we have also reduced in about half the required number of arc discharges.

In order to identify the cladding modes involved in these gratings we have simulated the dispersion curves for gratings arc-induced in these fibers. The modified phase matching condition has been used [27]. This permits to obtain the resonance wavelengths with an error lower than 0.1%:

\[
\beta_{o1}(\lambda) + s_0 \zeta_{01,01}(\lambda) - (\beta_{o,j}(\lambda) + s_0 \zeta_{0,j,0,j}(\lambda)) = \frac{2 \pi N}{\Lambda} \quad (1)
\]

where \(\beta_{o1}\) and \(\beta_{oj}\) are the propagation constants of the core and the j cladding modes respectively, \(\Lambda\) is the period of the grating, \(\zeta_{01,01}\) and \(\zeta_{0,j,0,j}\) are the self-coupling coefficients of the core and the j cladding modes, \(s_0\) is the coefficient of the first Fourier component of the grating and \(N\) is the diffraction order. For asymmetric coupling, \(1,j\) cladding modes must be considered [16, 27]:

\[
\beta_{o1}(\lambda) + s_0 \zeta_{01,01}(\lambda) - (\beta_{1,j}(\lambda) + s_0 \zeta_{1,j,1,j}(\lambda)) = \frac{2 \pi N}{\Lambda} \quad (2)
\]

The cladding index was modeled with the optical fiber cladding, made of fused silica, has been estimated with the well-known Sellmeier equation:

\[
n^2(\omega) = 1 + \sum_{j=1}^{\infty} \frac{B_j \omega_j^2}{\omega_j^2 - \omega^2} \quad (3)
\]

with parameters: \(B_1=0.691663\), \(B_2=0.4079426\), \(B_3=0.8974794\), \(\lambda_1=0.0684043\) μm, \(\lambda_2=0.1162414\), and \(\lambda_3=9.896161\), where \(\lambda_j=2\pi c/\omega_j\) and \(c\) is the speed of light in vacuum [28].

The optical fiber core refractive index of SMF28 for the simulations has been obtained, according to the specifications from Corning Inc., by increasing the refractive index of the cladding 0.357%. In order to obtain an optimized fit of the experimental and theoretical results, it was necessary to consider that an increase in the cladding refractive index was induced with the arc discharge and this effect depends on the grating period. For higher grating periods this effect was less important than for lower grating periods.

For the B/Ge co-doped fibers this fitting was not necessary. The same cladding index was used and the increase of the core

D. Sensitivity to External Refractive Index

In order to assess the sensitivity to the surrounding refractive index, several LPFGs were submitted to changes of the external refractive index in the range 1.33 to 1.42. To this purpose, each LPFG was glued on a special designed cuvette which keeps the fiber under a constant tension and avoids bending of the grating [29]. The LPFG transmission spectra were recorded, by using the optical arrangement described in Section II.B, after immersing the fiber in samples of water combined with different percentages of ethylene glycol. The refractive index of the different samples was calibrated using an Abbe refractometer with the sodium D line (589 nm). To avoid contamination in-between measurements, the fiber was cleaned with alcohol and dried naturally until recovering the initial LPFG transmission spectrum. It should be stressed that any environmental temperature change occurring during the 20 minutes of the experiment has a negligible effect on the temperature dependence of the refractive index of water-glycol mixtures [30].

Fig. 8a shows the spectrum of a 197 μm-LPFG, inscribed in the SMF28 fiber in the vicinity of the DTP, as a function of the surrounding refractive index. As it can be observed, as the refractive index of the external medium increases, the resonances belonging to the same cladding mode moves in opposite directions being the sensitivity larger for the one at longer wavelengths. This is a consequence of the larger slope of the resonance wavelength vs grating period curve above the DTP [4]. A similar behavior can be observed in Fig. 8b although in this case the 192 μm-LPFG is written in the B/Ge co-doped fiber in the DTP as is identified by the single resonance in air that afterwards splits in two when the grating is surrounded by water and water-glycol mixtures. Numerical results following the model used in Fig. 7b have been added to Fig. 8b (dashed lines), showing a good agreement with the experimental results. The refractive index used is reduced in 0.012 refractive index units (RIU) due to dispersion of glycol.
Fig. 9. Sensitivity to changes in the external refractive index of LPFGs near the DTP, inscribed in the (a) SMF28 fiber ($\Lambda=197 \, \mu m$); (b) B/Ge co-doped fiber #1.

and water in the infrared region [31], [32].

Fig. 9 shows the refractive index sensitivity for several gratings, with different periods, inscribed in the two fibers. As it is well-known the sensitivity increases as one approaches the cladding refractive index [9], nevertheless we present results for practical aqueous solutions (1.33 is the water RI). In the case of Fig. 9a, the result corresponds to the highest value obtained for a LPFG written in the SMF28 fiber, near the DTP. The sensitivity for the resonance at longer wavelengths is about two times higher (590 nm/RIU in the 1.33-1.41 RI range) than for the resonance at shorter wavelengths and is also two times higher than the value obtained for a 345 $\mu m$-LPFG [26]. As can be seen in Fig. 9b, the highest sensitivity was obtained for the 192 $\mu m$-LPFG written in the dispersion turning point in the B/Ge co-doped fiber #1, that is, a value of 720 nm/RIU in the 1.33-1.41 RI range, for the resonance at shorter wavelengths (a similar value was also obtained for the 148 $\mu m$-LPFG, for the resonance at longer wavelengths). It should be noted that the results obtained for the 148 $\mu m$-LPFG, for the resonance at shorter wavelengths, and for 192 $\mu m$-LPFG, for the resonance at longer wavelengths, are misleading due to some noise in the experimental data as can be observed, for instance, in Fig. 8b. In any case, by comparison of the 197 $\mu m$-LPFG, written in the SMF28 fiber, and the 192 $\mu m$-LPFG, written in the B/Ge #1 fiber, the sensitivity obtained for the resonance at shorter wavelengths (cladding modes: $LP_{1,11}$ vs $LP_{0,11}$) is three times higher for the grating written in the B/Ge fiber. The higher sensitivity obtained for gratings written in this fiber is in accordance with previous works [9], [33].

III. CONCLUSIONS

We have developed a high voltage power supply that permitted us to arc-induce LPFGs, in the DTP, in two B/Ge co-doped fibers and in one SMF28 fiber by using grating periods shorter than respectively, 150 $\mu m$ and 200 $\mu m$. We
have identified the cladding modes involved in the coupling by computer simulations. The fabricated LPFGs were characterized as a function of the external refractive index from 1.33 up to 1.42. In which concerns the SMF28 fiber, further work is still required in order to develop practical sensors based on LPFGs in the DTP. Currently, we are optimizing the fabrication of LPFGs written in the B/Ge co-doped fibers, in the DTP, with high sensitivity to be used at cryogenic temperatures and also as refractometer sensors comprising thin films in the transition region [34].
