1 **ABSTRACT**

2 The main goal of this study was to test the effect of [CO<sub>2</sub>] on C and N management in  
3 different plant organs (shoots, roots and nodules) and its implication in the  
4 responsiveness of exclusively N<sub>2</sub>-fixing and NO<sub>3</sub><sup>-</sup>-fed plants. For this purpose,  
5 exclusively N<sub>2</sub>-fixing and NO<sub>3</sub><sup>-</sup>-fed (10 mM) pea (*Pisum sativum* L.) plants were  
6 exposed to elevated [CO<sub>2</sub>] (1000 μmol mol<sup>-1</sup> versus 360 μmol mol<sup>-1</sup> CO<sub>2</sub>). Gas  
7 exchange analyses, together with carbohydrate, nitrogen, total soluble proteins and  
8 amino acids were determined in leaves, roots and nodules. The data obtained revealed  
9 that although exposure to elevated [CO<sub>2</sub>] increased total dry mass (DM) in both N  
10 treatments, photosynthetic activity was down-regulated in NO<sub>3</sub><sup>-</sup>-fed plants, whereas N<sub>2</sub>-  
11 fixing plants were capable of maintaining enhanced photosynthetic rates under elevated  
12 [CO<sub>2</sub>]. In the case of N<sub>2</sub>-fixing plants, the enhanced C sink strength of nodules enabled  
13 the avoidance of harmful leaf carbohydrate build up. On the other hand, in NO<sub>3</sub><sup>-</sup>-fed  
14 plants, elevated [CO<sub>2</sub>] caused a large increase in sucrose and starch. The increase in root  
15 DM did not contribute to stimulation of C sinks in these plants. Although N<sub>2</sub> fixation  
16 matched plant N requirements with the consequent increase in photosynthetic rates, in  
17 NO<sub>3</sub><sup>-</sup>-fed plants, exposure to elevated [CO<sub>2</sub>] negatively affected N assimilation with the  
18 consequent photosynthetic down-regulation.

## 1 1. Introduction

2

3 Current CO<sub>2</sub> concentration present in the atmosphere is limiting for C<sub>3</sub> photosynthesis,  
4 primarily because of the bifunctional nature of Rubisco and its low affinity for CO<sub>2</sub>  
5 (Bowes, 1993). Assuming that there are no other limitations, an increase in atmospheric  
6 [CO<sub>2</sub>] (C<sub>a</sub>) will increase photosynthesis through its direct effect on Rubisco (Bowes,  
7 1993; Farquhar et al., 1980). However, although the initial stimulation of net  
8 photosynthesis associated with elevated [CO<sub>2</sub>] is sometimes retained during long-term  
9 exposure to this gas (Rogers et al., 2004; Ainsworth et al., 2004), it is often partially  
10 reversed in an acclimation process often referred to as ‘downregulation’ (Ainsworth et  
11 al., 2002; Ainsworth and Rogers, 2007; Aranjuelo et al., 2011; Leakey et al., 2009b;  
12 Long et al., 2004).

13

14 The “capacity” to adjust C fixation with C requirements has been described as a key  
15 process conditioning photosynthetic performance under elevated [CO<sub>2</sub>] (Ainsworth et  
16 al., 2004; Aranjuelo et al., 2011; Ziska, 2008; Sanz-Sáez et al., 2010). According to  
17 these studies, when growth under elevated [CO<sub>2</sub>] conditions leads to an imbalance  
18 between C fixation and C requirements, plants decrease their photosynthetic rates to  
19 balance C source activity and sink capacity (Aranjuelo et al., 2011; Aranjuelo et al.,  
20 2009). From this point of view, the reduction in photosynthetic rates would be  
21 conditioned by a plant’s ability to develop new sinks (e.g. new vegetative or  
22 reproductive structures, enhanced respiratory rates), or to expand the storage capacity or  
23 growth rate of existing sinks. Previous studies (Serraj et al., 1998; Rogers et al., 2006)  
24 have postulated that legumes, since they are capable of fixing atmospheric N<sub>2</sub>, will have  
25 an advantage in plant growth over non-N<sub>2</sub>-fixing plants. According to previous studies

1 (Ainsworth et al., 2004; Davey et al., 2004; Rogers et al., 2009b), legumes might be  
2 able to overcome photosynthetic acclimation because of their ability to reset the balance  
3 of C and N metabolism under elevated [CO<sub>2</sub>]. According to Leakey et al. (2009a) the  
4 large C sink strength of nodules will avoid leaf carbohydrate build up. Arrese-Igor et al.  
5 (1999) observed that the greater photosynthetic rates of plants grown under elevated  
6 [CO<sub>2</sub>] conditions imply that a larger amount of photosynthetically derived organic  
7 carbon is supplied to nodules, where it is used by the nitrogenase enzyme in the  
8 bacteroid fraction within the nodules. This could be the reason why non-nodulated  
9 soybean plants undergo photosynthetic acclimation under elevated [CO<sub>2</sub>], whereas  
10 nodulated plants do not show a decrease in the CO<sub>2</sub> assimilation rate (Ainsworth et al.,  
11 2004). In non N<sub>2</sub>-fixing plants, the C sink/source is balanced by reducing Rubisco  
12 content, which leads to lower photosynthetic activity, making Rubisco derived N  
13 available for other N sinks

14

15 Although positive productivity and N<sub>2</sub> fixation responses to elevated [CO<sub>2</sub>] are common  
16 (Soussana and Hartwig, 1996; Lee et al., 2003; Feng et al., 2004), such a response is not  
17 universal. According to observations made from other studies (Sanz-Sáez et al., 2010;  
18 Hungate et al., 2004; West et al., 2005b; Aranjuelo et al., 2008), the possession of  
19 nodules did not avoid leaf carbohydrate build up with a consequent decrease in the  
20 photosynthetic capacity. It remains unclear why some studies show stimulation of N<sub>2</sub>  
21 fixation and plant growth under elevated [CO<sub>2</sub>] and others not. One possible explanation  
22 might be the fact that CO<sub>2</sub> x N<sub>2</sub> fixation differs depending on the species analyzed  
23 (West et al., 2005a; Rogers et al., 2009a). The second explanation could be the  
24 variability of environmental conditions such as temperature, water availability, N  
25 availability etc. (Serraj et al., 1998; Serraj et al., 1999; Erice et al., 2007).

1  
2 Experiments conducted under controlled (Stitt and Krapp, 1999) and field conditions  
3 (free air CO<sub>2</sub> enrichment, FACE; (Ainsworth and Long, 2005) have highlighted that C  
4 sink development is restricted under N limiting conditions. N limitation seems to be  
5 more marked in non N<sub>2</sub>-fixing plants than in N<sub>2</sub>-fixing plants. As observed by Taub et  
6 al. (2008), in non-legumes N concentration decreases between 10-14 % at elevated CO<sub>2</sub>  
7 (540-958 μmol mol<sup>-1</sup>) whereas in N<sub>2</sub>-fixing plants such as soybean only decreased 1.5  
8 %. The negative acclimation of photosynthesis may be the result of lowered leaf N  
9 content due to low soil N availability conditions (Theobald et al., 1998). In this sense, it  
10 has been suggested that a persistent increase in plant biomass production under elevated  
11 [CO<sub>2</sub>] can only be maintained by an increase in N uptake (Soussana and Hartwig, 1996;  
12 Feng et al., 2004). As a response to N availability limitations, plants exposed to elevated  
13 [CO<sub>2</sub>] have been described to invest a greater proportion of root biomass to explore a  
14 greater soil volume (Arndal et al. 2013). However, it should be also remarked that root  
15 nutrient uptake under elevated [CO<sub>2</sub>] have shown inconsistent patterns, due to  
16 differences in experimental protocols and species specific responses (Bassirrad 2000).  
17 There is evidence that the carbohydrate-mediated repression of photosynthetic genes is  
18 more severe in nitrogen deficient than in nitrogen replete plants (Long et al., 2004; Stitt  
19 and Krapp, 1999). According to Theobald et al. (1998), N assimilation cannot match  
20 CO<sub>2</sub> fixation, with a consequent carbohydrate build up and depletion of N content.  
21 According to Bloom et al. (2002; 2010), C compound accumulation is the consequence  
22 of depletion in NO<sub>3</sub><sup>-</sup> assimilation and N content. Since N<sub>2</sub> fixing plants are largely  
23 independent of soil N availability, they may become more competitive than non fixing  
24 plants in elevated CO<sub>2</sub> conditions (Feng et al., 2004; Lüscher et al., 1998). Although N<sub>2</sub>  
25 fixation costs are larger than for NO<sub>3</sub><sup>-</sup> assimilation (5.2-18.8 *versus* 2.5 g C g<sup>-1</sup> N;

1 Minchin and Witty 2005), as revealed by Kaschuk et al. (2010) the C costs of biological  
2 N<sub>2</sub> fixation might be compensated by increased photosynthesis and consequently  
3 enhanced plant growth.

4  
5 The aim of this study was to check whether the source of N is a major factor involved in  
6 C and N management in legumes and what implications it has for the responsiveness of  
7 photosynthetic performance under elevated [CO<sub>2</sub>] conditions. For this purpose,  
8 exclusively N<sub>2</sub>-fixing *versus* NO<sub>3</sub><sup>-</sup>-fed pea plants were exposed to elevated [CO<sub>2</sub>]  
9 conditions. In order to test the effect of [CO<sub>2</sub>] and N source on photosynthetic  
10 performance, we characterized shoot, root and nodule carbohydrate (sucrose, glucose,  
11 fructose and starch), amino acid, protein content and N content. As mentioned above,  
12 previous studies that have explored the responsiveness of N<sub>2</sub> fixing plants to  
13 environments with high [CO<sub>2</sub>] levels have mainly focused on leaf characterization.  
14 Although belowground organs have received comparatively little attention, due to the  
15 tight link between plant level C and N exchange further study will be the key to  
16 understanding the plant level responsiveness to predicted [CO<sub>2</sub>] scenarios.

17

## 18 **2. Material and Methods**

### 19 *2.1 Plant material and growth conditions*

20 The experiment was conducted with pea plants (*Pisum sativum* L. cv Frilene) grown in  
21 2.5 L plastic pots (one plant per pot) filled with 3:2 (v/v) vermiculite-perlite.  
22 Exclusively N<sub>2</sub> fixing pea plants were inoculated with *Rhizobium leguminosarum* biovar  
23 *viciae* NLV8. Plants were placed in two growth cabinets (Heraeus-Votsch HPS-500,  
24 Norrköping, Sweden) at 25/18°C (day/night) with a photoperiod of 16 hours at 480  
25 μmol m<sup>-2</sup> s<sup>-1</sup> photosynthetic photon flux density (PPFD) and a relative humidity of

1 70/80 % (day/night). The cabinets were fitted with two independent T-RH combined  
2 probes (41372VC/VF RM Young Co., Traverse City, MI, USA) connected to an  
3 external micro-processor (LI-1000; LiCor, Lincoln, Nebraska, USA). Plants were  
4 irrigated by a drip system, with N-free nutrient solution (Rigaud and Puppo, 1975) for  
5 N<sub>2</sub>-fixing plants and 10 mM KNO<sub>3</sub> for nitrate fed plants. In order to confirm that such  
6 KNO<sub>3</sub> content was not limiting for plant growth, during the last week of the experiment  
7 a set of additional plants was watered with 20 mM KNO<sub>3</sub> nutrient solution. The absence  
8 of differences in growth, and no reduction in N and NO<sub>3</sub><sup>-</sup> content confirmed that 10 mM  
9 was not limiting. Half of the randomly selected plants were placed into an elevated  
10 [CO<sub>2</sub>] cabinet where they were exposed to 1000 μmol mol<sup>-1</sup>, whereas the other half  
11 were placed in a cabinet where the [CO<sub>2</sub>] was set at 360 μmol mol<sup>-1</sup>. The [CO<sub>2</sub>]  
12 variation was within 20 μmol mol<sup>-1</sup> CO<sub>2</sub>. Air entered the cabinets from a compressor  
13 installed at the top of the building, and was filtered by four air filters (coarse-5 μm and  
14 1 μm Ø particle and 0.01 μm Ø particle physical filters and charcoal chemical filter) to  
15 prevent anomalous components. Cabinets were equipped with an infrared CO<sub>2</sub> analyzer  
16 (polytron-IRGA, Dragäer, Lübeck, germany) connected to a micro-processor located  
17 inside the cabinet. [CO<sub>2</sub>] was analyzed and controlled every second. All the  
18 determinations were conducted after 4 weeks of exposure to elevated [CO<sub>2</sub>] conditions.  
19 Both cabinets provided uniform air mixing and two independent T-RH combined probes  
20 in each of the cabinets were connected to an external microprocessor. To prevent  
21 temporary [CO<sub>2</sub>] changes within cabinets, plants were handled inside the cabinet by  
22 means of two windows installed at the glass door that allowed measurements without  
23 opening the cabinet's doors.

24

25 *2.2 Sampling and plant growth determinations*

1 Eighteen plants per treatment combination were harvested after four weeks of planting.  
2 For each plant, shoots, roots and nodules were weighed separately. Plant sampling was  
3 always carried out 5 hours after onset of the photoperiod. For plant growth  
4 determinations, samples were dried at 70 °C for 48 h in order to measure the dry matter  
5 (DM). Leaf surface area was determined with a LICOR 3100 leaf area meter (LICOR,  
6 Inc., Lincoln, NE).

7

### 8 *2.3 Gas exchange determinations*

9 Fully expanded apical leaves were enclosed in a Li-Cor 6200 gas exchange portable  
10 photosynthesis system (Li-Cor, Lincoln, Nebraska, USA). Determinations were  
11 conducted at 25 °C, 480  $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD, 70 % RH and at the corresponding growth  
12  $[\text{CO}_2]$ .

13

### 14 *2.4 Sugar, starch and total soluble proteins (TSP) content*

15 Shoot, root and nodule extracts were homogenized in a solution containing 80 % (v/v)  
16 ethanol that was heated until boiling. The hydroalcoholic phase was evaporated through  
17 a Turbovap (Zymark, Carmel, IN, USA) and resuspended with 4 mL of distilled water.  
18 The sample was centrifuged at 2.300 g for 10 minutes and the supernatant and the pellet  
19 were stored separately at -80 °C. Sucrose, glucose (Glc) and fructose (Fru) were  
20 determined in the supernatant fraction. Soluble sugar and starch content was determined  
21 in the pellet according to the method of Cabrerizo et al.(2001). Protein concentration  
22 was determined in the supernatant fraction using the Bradford Assay (Bio-Rad)  
23 (Aranjuelo et al., 2005).

24

### 25 *2.5 Amino acid content*

1 Leaf fresh material was exhaustively extracted in boiling 80% (v/v) ethanol. Ethanol-  
2 soluble extracts were dried in a Turbovap LV evaporator (Zymark Corp, Hopkinton,  
3 MA, USA) and soluble compounds were re-dissolved with 4 ml of distilled water, and  
4 mixed and centrifuged at 20000 g for 10 min. Free amino acids were assayed using the  
5 acid ninhydrin method of Yemm and Willis (1954).

6

### 7 *2.6 Nitrate ( $\text{NO}_3^-$ ) and reduced N ( $N_{\text{red}}$ ) content*

8 Nitrate content was determined in the soluble fraction described above for soluble sugar  
9 and organic acid content. The samples were injected into a capillary electrophoresis  
10 system (Beckman P/ACE system 5500, Beckman Instruments, Inc. CA, USA). The  
11 determinations were conducted with a -25 KV voltage at 25 °C using a photodiode  
12 detector with a 254 nm wavelength. The buffer used was composed of 2.25 mM  
13 pyromellitic acid, 6.5 mM NaOH, 0.75 mM hexamethonium hydroxide and 1.6  
14 triethanolamine with the pH adjusted to 7.7. Reduced  $\text{N}_2$  ( $N_{\text{red}}$ ) was determined with the  
15 Kjeldahl method (Aranjuelo et al., 2005). Plant N content (PNC) refers to plant N  
16 content, calculated as the sum of  $N_{\text{red}}$  and  $\text{NO}_3^-$ .

17

### 18 *2.7 Statistical analyses*

19 Data were processed by two-way analysis of variance (ANOVA) to test the effects of  
20  $[\text{CO}_2]$  and N nutrition using the statistical software package, SPSS 12.0 (SPSS Inc.,  
21 Chicago, IL, USA). The results were accepted as significant at  $P < 0.05$ . When  
22 differences between treatments ( $[\text{CO}_2]$  and/or N nutrition interactions) were significant  
23 according to the ANOVA analysis, least significant differences (LSD) were evaluated  
24 using Fisher's LSD test ( $P < 0.05$ ).

25

### 1 3. Results

2

3 Growth parameters revealed that regardless of [CO<sub>2</sub>], NO<sub>3</sub><sup>-</sup>-fed plants produced more  
4 total DM than the corresponding N<sub>2</sub>-fixing plants (Table 1). Under elevated [CO<sub>2</sub>], total  
5 DM increased by 71 and 111 % in N<sub>2</sub> fixing and NO<sub>3</sub><sup>-</sup>-fed plants, respectively (Table 1).  
6 Even if, elevated [CO<sub>2</sub>] and NO<sub>3</sub> fertilization increased shoot biomass, roots was only  
7 significantly affected by elevated [CO<sub>2</sub>] in NO<sub>3</sub><sup>-</sup>-fed plants (Fig. 1). Although exposure  
8 to 1000 μmol mol<sup>-1</sup> [CO<sub>2</sub>] increased nodule DM (Fig. 1), the number of nodules was not  
9 significantly affected by [CO<sub>2</sub>] enhancement (Table 1).

10

11 As shown in Fig. 2A, the responsiveness of photosynthetic rates (A<sub>n</sub>) to elevated [CO<sub>2</sub>]  
12 varied depending on the N source. In N<sub>2</sub> fixing plants A<sub>n</sub> increased, whereas in NO<sub>3</sub><sup>-</sup> fed  
13 plants no significant effect was observed. N source had no significant effect in A<sub>n</sub> .  
14 Exposure to elevated [CO<sub>2</sub>] increased A<sub>n</sub>/TSP by 48 and 177 % in N<sub>2</sub>-fixing and NO<sub>3</sub><sup>-</sup>-  
15 fed plants, respectively (Fig. 2.B). Although stomatal conductance (g<sub>s</sub>) was not affected  
16 by [CO<sub>2</sub>] in N<sub>2</sub>-fixing pea plants, in NO<sub>3</sub><sup>-</sup>-fed plants its values increased under 1000  
17 μmol mol<sup>-1</sup> [CO<sub>2</sub>] (Fig. 2C). As shown in Figure 2D, transpiration (T<sub>r</sub>) was unaffected  
18 in NO<sub>3</sub><sup>-</sup>-fed plants, but in N<sub>2</sub>-fixing plants its value diminished in plants grown under  
19 1000 μmol mol<sup>-1</sup> [CO<sub>2</sub>].

20

21 Exposure to elevated [CO<sub>2</sub>] increased sucrose content in all organs (Fig. 3A) but such  
22 an effect was more marked in NO<sub>3</sub><sup>-</sup>-fed than in N<sub>2</sub>-fixing plants. The largest increase  
23 was detected in leaves where its content increased by 56 and 366 % in N<sub>2</sub>-fixing and  
24 NO<sub>3</sub><sup>-</sup>-fed plants, respectively. Although glucose was not altered by [CO<sub>2</sub>] in the  
25 different organs, irrespective of the N treatment, it is remarkable that no glucose was

1 detected in  $\text{NO}_3^-$ -fed roots (Fig. 3B). Fructose content (Fig. 3C) diminished in the  
2 shoots of  $\text{NO}_3^-$ -fed plants and the nodules of  $\text{N}_2$ -fixing plants exposed to elevated  
3  $[\text{CO}_2]$ , with no significant differences observed in other organs. No fructose was  
4 detected in  $\text{NO}_3^-$ -fed roots. As shown in Figure 2D,  $[\text{CO}_2]$  enhancement increased the  
5 fructose content by 40 % in  $\text{N}_2$ -fixing plants and by 75 % in  $\text{NO}_3^-$ -fed shoots, with no  
6 significant differences recorded in roots of the other N treatment. Elevated  $[\text{CO}_2]$  effect  
7 in starch content was conditioned by N source form. Nodules were the only organ where  
8 elevated  $[\text{CO}_2]$  increased (82 %).

9  
10 The quantification of the plant N content (PNC) revealed that elevated  $[\text{CO}_2]$  was  
11 conditioned by N source. The PNC data also highlighted that while no differences were  
12 detected in elevated  $[\text{CO}_2]$  in  $\text{N}_2$ -fixing plants, in  $\text{NO}_3^-$ -fed plants the PNC decreased by  
13 15 %. Similar results were observed in the shoots for reduced N content ( $\text{N}_{\text{red}}$ ).  
14 Although at the root level there was no  $[\text{CO}_2]$  effect detected in the  $\text{N}_{\text{red}}$  content, it is  
15 remarkable that  $\text{N}_{\text{red}}$  values at both  $\text{CO}_2$  levels were larger in  $\text{NO}_3^-$ -fed plants than  $\text{N}_2$ -  
16 fixing plants.  $\text{N}_{\text{red}}$  was stimulated in nodules of  $\text{N}_2$ -fixing plants exposed to elevated  
17  $[\text{CO}_2]$ . Table 2 also shows that shoot and root  $\text{NO}_3^-$  was not affected by  $[\text{CO}_2]$  in  $\text{NO}_3^-$ -  
18 fed plants.

19  
20 Finally, as shown in Fig. 4A, the total soluble protein (TSP) content diminished by 14  
21 % in  $\text{N}_2$ -fixing plants and 87 % in  $\text{NO}_3^-$ -fed plants.  $[\text{CO}_2]$  effect in leaf TSP was  
22 modulated by N source. Although under ambient  $[\text{CO}_2]$  conditions, TSP was larger in  
23  $\text{NO}_3^-$ -fed plants, under elevated  $[\text{CO}_2]$  TSP content was larger in  $\text{N}_2$ -fixing plants. The  
24  $[\text{CO}_2]$  effect on amino acid content was similar in both N treatments, and varied  
25 depending on the organ analyzed (Fig. 4B). Whereas in shoots the amino acid content

1 decreased under  $1000 \mu\text{mol mol}^{-1}$   $[\text{CO}_2]$ , in roots no significant differences were  
2 observed.

3

#### 4 **4. Discussion**

5

6 Our study showed that  $[\text{CO}_2]$  interacted N source form, being  $\text{NO}_3^-$ -fed plants the ones  
7 that produced more DM than the corresponding  $\text{N}_2$ -fixing plants. Under both ambient  
8 and elevated  $[\text{CO}_2]$  such increase was more marked in roots (108 and 104 %  
9 respectively) than in shoots (50 and 29 % respectively). Furthermore, the fact that in  
10  $\text{NO}_3^-$ -fed plants exposed to elevated  $[\text{CO}_2]$  the increase in root DM was larger than that  
11 in shoots, suggests that those plants invested more photoassimilates to root biomass in  
12 order to explore a greater soil volume. Such investment would be explained by the N  
13 necessity of those plants. These results highlight the relevance of analyzing  
14 belowground organ growth.

15

16 The absence of significant differences in photosynthetic ( $A_n$ ) activity of  $\text{NO}_3^-$ -fed *versus*  
17  $\text{N}_2$ -fixing plants, revealed that the larger DM of  $\text{NO}_3^-$ -fed plants (compared with the  
18 corresponding  $\text{N}_2$ -fixing plants) was caused by their higher plant level photosynthetic  
19 rates. The fact that  $\text{NO}_3^-$ -fed plants had more leaf area implied that, as described  
20 previously (Aranjuelo et al., 2005), they were capable of fixing more  $\text{CO}_2$  at the plant  
21 level with a consequent increase in plant growth. Interestingly, gas exchange data also  
22 revealed that the  $[\text{CO}_2]$  affected photosynthetic activity differently in  $\text{N}_2$ -fixing and  
23  $\text{NO}_3^-$ -fed plants. Although  $A_n$  increased in  $\text{N}_2$ -fixing plants grown at  $1000 \mu\text{mol mol}^{-1}$ ,  
24 in the case of  $\text{NO}_3^-$ -fed plants, exposure to elevated  $[\text{CO}_2]$  had no significant effect on  
25  $A_n$ . Previous results obtained in studies analyzing plant growth and photosynthetic

1 activity (Rogers et al., 2004; Ainsworth and Long, 2005; Aranjuelo et al., 2005;  
2 Ainsworth and Bush, 2011a) highlight the fact that photosynthetic activity under  
3 elevated [CO<sub>2</sub>] does not always increase and depends on exposure time, plant species  
4 and limiting environmental conditions. The reduction in Rubisco carboxylation capacity  
5 could be caused by stomatal and/or non-stomatal limitations of photosynthesis. Gas-  
6 exchange measurements showed that leaf conductance ( $g_s$ ) was not affected (N<sub>2</sub>-fixing  
7 plants) or increased (NO<sub>3</sub><sup>-</sup>-fed plants), which implies that plants grown under elevated  
8 [CO<sub>2</sub>] conditions had a higher intercellular CO<sub>2</sub>. Photosynthetic non-stomatal limitation  
9 may be caused by a diminishment in the Rubisco protein content (Urban 2003).  
10 Although total soluble protein (TSP) content decreased under both forms of N supply,  
11 such diminishment was much more marked in the NO<sub>3</sub><sup>-</sup>-fed plants (47 %) than in the  
12 N<sub>2</sub>-fixing plants (12 %). Although Rubisco was not quantified in this study, because  
13 Rubisco might represent up to 30 % of TSP (Aranjuelo et al., 2005) it is very likely that  
14 under elevated [CO<sub>2</sub>] there was also a decrease in Rubisco content. The fact that plants  
15 exposed to 1000 μmol mol<sup>-1</sup> CO<sub>2</sub> had larger (48 and 177 % per N<sub>2</sub>-fixing and NO<sub>3</sub><sup>-</sup>-fed  
16 plants, respectively) A<sub>n</sub>/TSP revealed that these plants improved their Rubisco  
17 carboxylation efficiency under elevated [CO<sub>2</sub>] (Ainsworth and Rogers, 2007).

18

19 A frequent acclimation response is the accumulation of leaf carbohydrates in elevated  
20 [CO<sub>2</sub>] (Ainsworth et al., 2004; Long et al., 2004; Sanz-Sáez et al., 2010; Moore et al.,  
21 1999). The fact that in the NO<sub>3</sub><sup>-</sup>-fed plants the increase in the concentration of shoot  
22 sucrose (366 %) was much larger than in the corresponding N<sub>2</sub>-fixing plants (56 %)  
23 revealed that this large accumulation in leaf photoassimilates was involved in the  
24 photosynthetic down-regulation of NO<sub>3</sub><sup>-</sup>-fed plants. Sucrose, together with starch,  
25 represent the major forms of leaf cellular carbohydrate storage. Leaf sucrose content

1 may reflect the balance of C sink/source demand (Long et al., 2004). In this sense,  
2 starch has also been proposed as a buffer for sucrose metabolism that might minimize  
3 leaf sucrose cycling (Moore et al., 1999; Stitt et al., 2010). According to these authors,  
4 when there is a sink limitation under elevated [CO<sub>2</sub>] the plants increase their starch sink  
5 strength. Our data confirmed that starch accumulation was more marked in the shoots of  
6 NO<sub>3</sub><sup>-</sup>-fed (75 %) than in the corresponding N<sub>2</sub>-fixing plants (40 %) exposed to elevated  
7 [CO<sub>2</sub>]. Leaf carbohydrate levels are conditioned by metabolic activity, storage processes  
8 and the sink strength of the other plant organs (Aranjuelo et al., 2011; Moore et al.,  
9 1999). Sucrose is the main form of translocated C in most plants and the main substrate  
10 for sink limitation. The analyses of sucrose content in belowground organs increased in  
11 N<sub>2</sub>-fixing (44 and 24 % in roots and nodules) and NO<sub>3</sub><sup>-</sup>-fed (457 %) plants exposed to  
12 elevated [CO<sub>2</sub>]. The increase in starch content of N<sub>2</sub>-fixing (51 and 82 % in roots and  
13 nodules) and NO<sub>3</sub>-fed roots (145 %) highlighted that, especially in NO<sub>3</sub><sup>-</sup>-plants, roots  
14 represented a major C sink under elevated [CO<sub>2</sub>].

15

16 Our data revealed that although N<sub>2</sub>-fixing plants were capable of maintaining plant level  
17 N content (PNC) under elevated [CO<sub>2</sub>], in the case of NO<sub>3</sub><sup>-</sup>-fed plants such content  
18 decreased by 15 %. Furthermore, the reduced N (N<sub>red</sub>) data of different organs revealed  
19 that the diminishment in N content of NO<sub>3</sub><sup>-</sup>-fed plants exposed to 1000 μmol mol<sup>-1</sup>  
20 [CO<sub>2</sub>] was explained by the lower leaf N content. The fact that NO<sub>3</sub><sup>-</sup> content was not  
21 affected by [CO<sub>2</sub>] revealed that the lower shoot N content was caused by the depletion  
22 of N assimilation in NO<sub>3</sub><sup>-</sup>-fed plants exposed to elevated [CO<sub>2</sub>]. The decrease in shoot  
23 amino acid content of these plants also confirmed such down-regulation in N  
24 assimilation. NO<sub>3</sub><sup>-</sup> assimilation takes place essentially in aboveground organs (Gonzalez  
25 et al., 1996), where the nitrate reductase activity is regulated by carbohydrate content

1 and light (Redinbaugh et al., 1996). According to Reich et al. (2006), Norby et al.  
2 (2001) and Hungate et al. (2003), N assimilation cannot match CO<sub>2</sub> fixation, with the  
3 consequent carbohydrate build up and depletion in N content, and (Bloom et al., 2002)  
4 described that CO<sub>2</sub> fixation interferes with NO<sub>3</sub><sup>-</sup> assimilation. According to these  
5 studies, reduction of NO<sub>2</sub><sup>-</sup> to NH<sub>4</sub><sup>+</sup> and the amino acid compete with starch for the  
6 availability of ferredoxin required for both processes. In agreement with previous  
7 findings (Ezquer et al., 2010a), our data reveal that exposure to elevated [CO<sub>2</sub>] in NO<sub>3</sub><sup>-</sup>-  
8 fed plants was favoured over amino acid assimilation (Li et al., 2011; Ezquer et al.,  
9 2010b; Yamakawa and Hakata, 2010).

10

11 Concerning N<sub>2</sub>-fixing plants, although under elevated [CO<sub>2</sub>] conditions PNC matched  
12 the values obtained in NO<sub>3</sub><sup>-</sup>-fed plants, it is remarkable that under ambient [CO<sub>2</sub>] that  
13 the N content was lower in N<sub>2</sub>-fixing than in NO<sub>3</sub><sup>-</sup>-fed plants. The absence of significant  
14 N fertilization differences in PNC under 1000 μmol mol<sup>-1</sup> [CO<sub>2</sub>] reveals that under  
15 ambient [CO<sub>2</sub>] conditions the nodules might have had C limitations that conditioned the  
16 level of N<sub>2</sub> fixation in these plants. Such limitations were overcome under elevated  
17 [CO<sub>2</sub>]. In relation to the [CO<sub>2</sub>] effect in N<sub>2</sub>-fixing plants, the absence of significant  
18 differences in the PNC and N<sub>red</sub> values of N<sub>2</sub>-fixing plants under elevated [CO<sub>2</sub>] showed  
19 that, in contrast to the observation in NO<sub>3</sub><sup>-</sup>-fed plants, nodules were capable of matching  
20 the N requirements of such plants (Rogers et al., 2006; Cabrerizo et al., 2001). Despite  
21 the larger DM (increased 71 %), the lack of any detectable differences in PNC revealed  
22 that N<sub>2</sub> fixation was increased under elevated CO<sub>2</sub> conditions. The larger nodule DM,  
23 together with the increase in nodule sucrose (24 %) and starch (82 %) confirmed that  
24 the increased photosynthetic rate and level of photoassimilates enabled the improvement

1 in N<sub>2</sub> fixation by those plants. These results highlight the relevance of nodules as a  
2 major C sink.

3

#### 4 **5. Conclusion**

5

6 In summary, our study highlighted the relevance of the relationship of leaf performance  
7 under elevated [CO<sub>2</sub>] to other organs such as roots and nodules. Although in both N<sub>2</sub>-  
8 fixing and NO<sub>3</sub><sup>-</sup>-fed plants exposure to 1000 μmol mol<sup>-1</sup> CO<sub>2</sub> increased plant growth,  
9 gas exchange data revealed that N<sub>2</sub>-fixing plants were capable of maintaining enhanced  
10 photosynthetic rates, whereas in the case of NO<sub>3</sub><sup>-</sup>-fed plants, photosynthetic activity was  
11 down-regulated. Our data highlighted that in NO<sub>3</sub><sup>-</sup>-fed plants exposed to elevated [CO<sub>2</sub>],  
12 starch formation prevailed over NO<sub>3</sub><sup>-</sup> assimilation with consequent limitations in leaf N  
13 content. Such results reveal that, under elevated [CO<sub>2</sub>], NO<sub>3</sub><sup>-</sup>-fed plants will require  
14 large N fertilization levels so to overcome photosynthetic down-regulation. The  
15 overcoming of photosynthetic acclimation of N<sub>2</sub>-fixing plants was explained by their  
16 avoidance of excessive leaf carbohydrate build up. The large C requirements of the  
17 nodules enabled avoidance of large photoassimilate accumulation. Furthermore, even  
18 though the limited C availability under ambient [CO<sub>2</sub>] limited the N content in N<sub>2</sub>-fixing  
19 plants, the nodules' C sink requirements under elevated [CO<sub>2</sub>] were fulfilled by the  
20 enhanced photosynthetic and photoassimilate availability of these plants. In the other  
21 hand, despite their larger DM, PNC data showed that NO<sub>3</sub><sup>-</sup>-fed plants exposed to  
22 elevated [CO<sub>2</sub>] had N limitations that conditioned photosynthetic performance. In  
23 contrast to the nodules, the larger root DM of NO<sub>3</sub><sup>-</sup>-fed plants did not enable the  
24 maintenance of control N and photoassimilate levels.

**FIGURE LEGENDS**

**Figure 1.** Effect of exposure to elevated CO<sub>2</sub> (1000 *versus* 360 μmol mol<sup>-1</sup>) on shoot dry matter (DM, g plant<sup>-1</sup>), root DM (g plant<sup>-1</sup>) and, nodule DM (DM, mg plant<sup>-1</sup>) determined in exclusively N<sub>2</sub>-fixing (N<sub>2</sub>-fix) *versus* nitrate-fed (NO<sub>3</sub><sup>-</sup>-fed) pea plants (*Pisum sativum* L.). Each value represents the mean of 18 replicates ± SE. Each value represents the mean of 4 replicates ± SE. A two-way ANOVA was used to test [CO<sub>2</sub>] and/or N source (N) effect and their interaction (CO<sub>2</sub> x N). The different letters represent significant differences between average values at P = 0.05. n.s. refers to non significant differences.

**Figure 2.** Effect of exposure to elevated CO<sub>2</sub> (1000 *versus* 360 μmol mol<sup>-1</sup>) on net photosynthesis (A; A<sub>n</sub>, μmol CO<sub>2</sub> m<sup>-2</sup> s<sup>-1</sup>), A<sub>n</sub>, and the total soluble protein ratio (B; A<sub>n</sub>/TSP), stomatal conductance (C; gs, mol H<sub>2</sub>O, m<sup>-2</sup> s<sup>-1</sup>) and transpiration (D; Tr, mol H<sub>2</sub>O, m<sup>-2</sup> s<sup>-1</sup>) determined in exclusively N<sub>2</sub>-fixing (N<sub>2</sub>-fix) *versus* nitrate-fed (NO<sub>3</sub><sup>-</sup>-fed) pea plants (*Pisum sativum* L.). Each value represents the mean of 4 replicates ± SE. A two-way ANOVA was used to test [CO<sub>2</sub>] and/or N source (N) effect and their interaction (CO<sub>2</sub> x N). The different letters represent significant differences between average values at P = 0.05. n.s. refers to non significant differences.

**Figure 3.** Effect of exposure to elevated CO<sub>2</sub> (1000 *versus* 360 μmol mol<sup>-1</sup>) on leaf, root and nodule sucrose (A), glucose (B), fructose (C) and starch (D) content (mg g<sup>-1</sup>) determined in exclusively N<sub>2</sub>-fixing (N<sub>2</sub>-fix) *versus* nitrate-fed (NO<sub>3</sub><sup>-</sup>-fed) pea plants (*Pisum sativum* L.). Each value represents the mean of 4 replicates ± SE. A two-way ANOVA was used to test [CO<sub>2</sub>] and/or N source (N) effect and their interaction (CO<sub>2</sub> x N). The different letters represent significant differences between average values at P = 0.05. n.s. refers to non significant differences. n.d. refers to non-detectable data.

**Figure 4.** Effect of exposure to elevated CO<sub>2</sub> (1000 *versus* 360 μmol mol<sup>-1</sup>) on leaf and root total soluble protein (A; TSP, mg g<sup>-1</sup>) and amino acid (B; Aa, μmol g<sup>-1</sup>) content determined in exclusively N<sub>2</sub>-fixing (N<sub>2</sub>-fix) *versus* nitrate-fed (NO<sub>3</sub><sup>-</sup>-fed) pea plants (*Pisum sativum* L.). Each value represents the mean of 4 replicates ± SE. A two-way ANOVA was used to test [CO<sub>2</sub>] and/or N source (N) effect and their interaction (CO<sub>2</sub> x N). The different letters represent significant differences between average values at P = 0.05. n.s. refers to non significant differences.

1 **Table 1.** Effect of exposure to elevated CO<sub>2</sub> (1000 *versus* 360 μmol mol<sup>-1</sup>) on total dry matter (DM, g plant<sup>-1</sup>), the root/shoot ratio and nodule  
 2 number (plant<sup>-1</sup>) determined in exclusively N<sub>2</sub>-fixing (N<sub>2</sub>-fix) *versus* nitrate-fed (NO<sub>3</sub><sup>-</sup>-fed) pea plants (*Pisum sativum* L.). Each value represents  
 3 the mean of 18 replicates ± SE. A two-way ANOVA was used to test [CO<sub>2</sub>] and/or N source (N) effect and their interaction (CO<sub>2</sub> x N). The  
 4 different letters represent significant differences between average values at P = 0.05. n.a. refers to not applicable analyses.
