Abstract— The low-cost and compactness of transmit-array antennas (TAs) make them attractive for 5G backhaul links. However, the TA advantage is less obvious when considering the broadband operation requirement. Two main factors influence the bandwidth performance: i) the bandwidth of the unit cells; ii) the number of 360° phase wrapping zones in the aperture, which are designed for a specific frequency. Herein, we overcome these limitations by using all-dielectric unit cells (inherently broadband) and by developing a general method to quantify and manage the intricate relation between antenna gain, bandwidth and antenna height. Based on this framework we optimize, as an example, a TA design (focal distance, $F = 63 \text{ mm}$ and aperture diameter $D = 80 \text{ mm}$) to comply with typical gain specification for 5G backhaul links (>30 dBi) in the WiGiG band (from 57 to 66 GHz). The feed is a dedicated compact horn ($8 \times 5 \times 22 \text{ mm}^3$) that provides a proper illumination of the aperture. Additive manufacturing is used to simplify the manufacturing process of the antenna. A very good agreement between simulations and experimental results is obtained, achieving good aperture efficiency for this type of antenna (42%), which rivals with existing solutions based on more expensive manufacturing techniques.

Index Terms—5G backhaul link, WiGiG band, Transmit-Array, V-band Horn antenna, Additive manufacturing

I. INTRODUCTION

THE massification of 5G will pivot on cost-effective technologies that can support the development of the Enhanced Mobile Broadband (eMBB) platform. In the context of pico and femto cells, that will constitute the landscape of future 5G mobile communications, extremely low-cost backhaul links between base stations and access points are required. Millimeter-waves (mmW) provide the necessary throughputs with extremely low deployment cost when compared with fiber optics-based backhaul solutions. In particular, the WiGiG band from 57 to 66 GHz, offers large

bandwidths over unlicensed spectrum and high frequency reuse capability, ideal in dense cell environments [1]. The electronics industry is responding to this current need of increasing the operating frequency by providing new chipset mmW antenna-modules [2]-[4]. Phased-array configurations could be an alternative, but they lead to excessive feeding network losses and their cost scales with gain and frequency [5]. [6] as well as DC consumption. Progress has been made on commercial integrated high gain antenna solutions for V-band [7], however, the cost of these antennas is still the main bottleneck. High fabrication precision is required to meet the tolerances, which impacts the antenna cost. Therefore, the antenna design should also aim for a simple fabrication process. The ongoing development of additive manufacturing can offer new possibilities for cost reduction. For example, dielectric lens-based solutions can benefit from the low-cost of fused deposition modeling (FDM) technique, or injection molding in mass production. The drawback is that materials used in these technologies tend to be lossy, such as ABS-M30 ($\epsilon_r = 2.48, \tan \delta = 0.009$)).

An intensive research effort is being carried out to achieve a solution that can deliver high gain (typically above 30 dBi [1]) in the entire WiGiG band [8], [9] with the lowest possible cost. In [8], the authors integrated a 3D printed elliptical chopped dielectric lens with a FR4 PCB antenna-source to favor gain enhancement at low-cost. However, the gain performance of this solution was limited by the radiation efficiency of the FR4 primary feed antenna and by the dielectric losses of the lens material. In [10], the authors showed that those losses could be reduced by using a transmit-array (TA) lens – sometimes designated as discrete dielectric lens (DDL). We showed that the antenna radiation efficiency increased from 60% to 83% when a PLA chopped elliptical lens was replaced by an equivalent PLA TA. Other 3D printed DDL designs can be found in the literature [11]-[17]. Achieving high gain is quite

straightforward, however, the challenge is to overcome the bandwidth limitation caused by the number of 360° phase jump zones that directly correlates with the F/D ratio. In [13] the bandwidth problem was solved by increasing the focal distance until lens zoning disappears. This leads to large focal lengths ($F/D = 2.8$) which impacts on the antenna height. A clever scheme is proposed in [13] to reduce the focal distance by a factor of 3 using a polarization rotation reflection surface and polarization grid. However, these antennas become inherently single polarization and the additional complexity of the configuration impacts on the antenna-system and terminal cost.

In this work, we present a design procedure for dielectric TAs antennas (or DDL) that optimize the compromise between F/D ratio, gain and bandwidth. We use our guidelines to show that an all-dielectric TA antenna can be a viable affordable option to meet the specifications for broadband backhaul connections at V-band. The unit cell design procedure of TAs provides a fresh perspective into the classical topic of Fresnel Zone Plate Lens [14]. Applying the same approach used in [23] to evaluate the scanning performance of a metal-based multilayered TA, we demonstrate that it is possible to achieve a closed-form expression that accurately captures the relation between gain, bandwidth and focal distance. The simplicity of this method contrasts with the complexity of the GO/PO integral formulation used in [15] for FZPL. Furthermore, it provides a direct relation between gain and bandwidth that is not captured by the usual approach of imposing a maximum phase error criteria [16].

A compact 3D-printed metal-coated polymer corrugated horn antenna is also specially designed to provide proper illumination of the lens. Metal 3D printed corrugated horns exhibit good performances at W band or even up to 300 GHz [18]–[20], but the metal coating of 3D-printed polymer parts is a more affordable technique [20]. As the frequency increases, this process becomes more challenging due to the increase of sensitivity to the surface roughness and coating conductivity, but thanks to the current evolution of this technology [21], it is now a cost-effective alternative for V-band.

This demonstrates that the whole antenna production can be based on additive manufacturing, leading to a compact ($F/D = 0.8$) antenna system at the V-band with high gain (>30 dBi) and good aperture efficiency (42%).

In section II, the design guidelines for a DDL are provided based on a GO/PO analysis. In section III, we implement these guidelines to design an antenna (feed and lens) compliant with the gain specifications for WiGiG 5G backhaul links. Finally, section IV addresses the measured results.

II. DIELECTRIC TRANSMIT-ARRAY

In a TA each portion of the aperture acts as a spatial phase shifter – the unit cell – that adds to the incoming phase ϕ_{in} , a prescribed phase delay ϕ_{lens} , such that $\phi_{out} = \phi_{in} + \phi_{lens}$. The unit cells are designed as if the rays passing through the lens are perpendicular to its surface, which can be a reasonable approximation for low lens thicknesses and low incidence angles (Fig. 1). In this work, the unit cell is a parallelepiped with

height h_{max} , composed of a dielectric (ABS-M30) with height h , and air (occupying the remaining volume). The control of the unit cell phase shift is obtained by varying the dielectric height h , where ϵ_r is the real part of the dielectric permittivity and k_0 is the free-space wavenumber. Considering a minimum height different from zero avoids having a lens composed by separated annular regions. Herein, we consider $h_{min} = 1$ mm, which is enough for the lens structural integrity. On the other hand, the height h_{max} is fixed to provide the usual 360° phase span in TA design for a given wavelength λ_0 . The aperture is designed to produce boresight collimation by distributing the unit cells according to the profile

$$h(r) = h_0 + \frac{F - \Delta l + m\lambda_0}{\sqrt{\epsilon_r} - 1}, R_m < r < R_{m+1} \quad (1)$$

Where h_0 is the central height of the lens ($r = 0$), $\Delta l = \sqrt{r_i^2 + F^2} - F$ (see Fig. 1) and m defines the zone of the lens up to a total of K zones. The radial positions of the transitions between zones are defined by the condition $h(R_m) = h_{min}$. We considered the typical half wavelength unit cell size, $w = 2.5$ mm ($\frac{\lambda_0}{2}$ @ 60 GHz) resulting in the stepwise lens profile given in Fig. 1. The radial symmetry of this problem allows assembling the lens using concentric annuli with fixed widths w , as represented in the inset of Fig. 1. The diffraction effects are then reduced when compared with a fully pixelized version of the lens.

Fig. 1. Working principle of a dielectric transmit-array for beam collimation.

The outgoing electric field from the TA in a plane of constant phase (green dashed lines in Fig. 1) can be approximated by Gaussian amplitude distribution with standard deviation σ

$$\vec{E}_{ab}(r) \approx e^{-\frac{r^2}{2\sigma^2}} e^{j\Phi_{out}} \vec{u}_E. \quad (2)$$

where Φ_{out} varies with wavelength as a stepwise function

$$\Phi_{out} = -2\pi m \frac{\lambda_0}{\lambda}, R_m < r < R_{m+1}. \quad (3)$$

With $m = \{0, 1, \dots, K\}$. The standard deviation σ is related to the taper level, τ_{dB} , $E_{ab}(r = D/2) = 10^{-\tau_{dB}/20}$. The typical taper value is $\tau_{dB} = 10$ dB which ensures a good compromise between losses due to the spillover and sub-illumination of the aperture. As the position of the 360° phase transitions depends on the operating frequency, phase errors build-up as the number of lens zones increases. Considering the Gaussian

approximation, the integration of the fields of the aperture can be done analytically using GO/PO analysis. The directivity for the boresight direction can then be calculated explicitly

$$D_{max} = D_{ir0} \left| \frac{\sum_{m=0}^K e^{-j\frac{2\pi m \lambda_0}{\lambda}} \left(e^{-\frac{R_m^2}{2\sigma^2}} - e^{-\frac{R_{m+1}^2}{2\sigma^2}} \right)}{1 - e^{-\frac{D^2}{4\sigma^2}}} \right|^2. \quad (4)$$

Where

$$D_{ir0} = s_{TA} \left(\frac{4\pi\sigma}{\lambda} \right)^2 \tanh \left[\left(\frac{D}{4\sigma} \right)^2 \right] \quad (5)$$

is the directivity of a circular aperture with constant phase ($\lambda = \lambda_0$) and Gaussian illumination, as in Eq.8 of [23]. R_m is defined by $h_i(R_m) = h_{min}$ with $m = \{0, 1, \dots, K\}$ and since the last zone can be truncated, $R_{K+1} = D/2$. We introduce the parameter s_{TA} as the TA scaling factor that accounts for other effects that were not considered in this GO/PO analysis, such as unit cell reflection and insertion losses, aperture illumination spillover and phase errors caused by refraction and diffraction (which are more significant near the lens 360° phase transitions). Looking at a wide variety of different types of TAs, s_{TA} is typically below 50% [23]. Therefore, we considered $s_{TA} = 3$ dB for the design process. As shown in [10], the radiation efficiency of these dielectric TAs is high, allowing to approximate the antenna gain by its directivity. The aperture dimension and the focal distance can then be defined from a given gain and bandwidth criteria according to (4) and (5).

III. DESIGN OF A TRANSMIT-ARRAY LENS FOR WiGiG BAND

An antenna for 5G backhaul wireless links needs to deliver high gain, typically above 30 dBi [1]. WiGiG band usually refers to the [57-66] GHz band according to 802.11.ad standard, but recently an extended WiGiG band was defined (802.11.ay) covering [57-70] GHz (see inset of Fig. 2)

A. TA design

We set a 31 dBi directivity D_0 , to give a 1 dB margin to accommodate the bandwidth limitation of the TA in the specified gain criteria. The aperture dimension follows from: $D_0(D) = 31$ (dBi) $\rightarrow D \approx 80$ (mm). The maximum number of phase transitions is determined by the F/D ratio, where F is the focal distance. For this aperture size, we use equation to estimate the minimum focal distance that complies with the 30-dBi minimum gain criteria of the WiGiG band. By setting $h_0 = h_{max}$ the radius of the first lens zone ($m = 0$), which has no bandwidth limitation, is maximum. Neglecting second order effects, this condition maximizes the lens bandwidth as well. Later, full-wave simulations are employed to tune this parameter, further optimizing the gain and lens bandwidth. In this case, the phase transition occurs at $R_m = \sqrt{m^2 \lambda_0^2 + 2F \lambda_0 m}$. In Fig. 2 we plot for several F/D ratios and select the minimum value that complies with the gain criteria for the extended WiGiG band, corresponding to $F/D = 0.8$. Fig. 2 captures the interplay between the dependence of D_{max} with frequency and the gain degradation due to the phase error

caused by the zoning process. For $F/D > 2$ no zoning occurs ($K = 0$) thus $D_{max} = D_0$.

Fig. 2. PO/GO directivity D_{max} variation with frequency, Eq. , for different focal distances considering $D = 80$ mm $\tau_{dB} = 10$ dB and $s_{TA} = 3$ dB

B. Feed performance

According to the designed DDL lens, a focal ratio $F/D = 0.8$ and $\tau_{dB} = 10$ dB taper level implies a 13 dBi feed directivity [23]. A dedicated compact corrugated horn antenna was designed and fabricated ($8 \times 5 \times 22$ mm). It is wideband and has a stable radiation pattern in the WiGiG band (57-66 GHz). The performance of this design is shown in Fig. 3. A 13 dBi co-pol gain was achieved in the entire WiGiG band from 56 to 67 GHz, with high radiation efficiency ($>85\%$), low cross polarization (>27 dB), and good polarization purity (>27 dBi). Measured and simulated gains agree very well.

Fig. 3. Radiation patterns of the manufactured horn antenna .

IV. ANTENNA MEASUREMENTS

The measurement campaign for the radiation patterns was conducted in our in-house measurement system: a spherical measurement range capable of performing amplitude-only acquisitions up to 140 GHz at fixed distances of 20 cm, 40 cm and 60 cm (Fig. 4 a). Considering the main diagonal of the lens, the far-field (FF) distance at 66 GHz is 6.13 m. Thus, it is necessary to resort to near-field to far-field (NF-FF) transformation techniques to obtain the radiation pattern. The employed phaseless NF-FF algorithm is based on the *phaseless Sources Reconstruction Method* (pSRM) [24]. The pSRM is an iterative phaseless technique which relies on the spatial variability of the NF with distance and, therefore, it requires amplitude information from two or more NF acquisition surfaces. The main advantage of iterative techniques is that they do not require any modification of the measurement setup with

respect to a regular FF acquisition. However, there is a risk of stagnation of the algorithm due to the use of iterative solvers for nonlinear systems of equations. This risk becomes higher when the variability of the field within the NF acquisition surfaces is low, as might be the case with lens antennas, yielding less accurate FF results. The field amplitude is acquired at two spherical surfaces with radii of 40 cm and 60 cm. The sampling rate is $\lambda/4$ at the highest frequency of the band, 66 GHz, as required to perform phaseless NF-FF transformations [25]. Due to mechanical restrictions of the setup, the acquisition surfaces are truncated to a ϕ and θ angular range of $[-25^\circ, 25^\circ]$, yielding a valid margin of the FF data of $[-14^\circ, 14^\circ]$ in both axes [25]. In Fig. 5 the FF amplitude and phase of the copolar component of the field, computed from the NF phaseless acquisitions is compared with full-wave simulation for the E-plane of the copolar component. The agreement between measurements and simulations is good within the valid margin area, shaded in grey. The main sources of the retrieval error are related to the truncation of the acquisition planes and the accuracy of the phase retrieval method and, to a lesser extent, mechanical deviations of the robotic arms and random errors of the RF instrumentation. Finally, the antenna gain was computed by means of the well-known intercomparison method [26] with a standard gain horn. The method is adapted for NF acquisitions in order to compensate the variation introduced by the NF-FF transformation to the radiation pattern and thus, the gain is given by $G_{lens,FF} = G_{lens,NF} + (D_{lens,FF} - D_{lens,NF})$, where $G_{lens,NF}$ is the measured gain in NF, 27.16 dBi at 60 GHz. $D_{lens,FF}$ and $D_{lens,NF}$ are directivities from FF and NF respectively, computed from pattern integration of the extracted FF pattern by means of the pSRM and the truncated NF amplitude-only acquisitions respectively. The obtained values at 60 GHz are 34.67 and 29.95 dBi, yielding a FF gain value of 31.9 dBi. The final FF gain values for the rest of the studied frequencies are gathered in Fig. 6 and compared with the results obtained from full-wave simulations and the PO/GO analysis. Based on previous measuring experiences, we estimate that the uncertainty of measured gain is ± 1.2 dB (corresponding to the error bars in Fig. 6), which is in line with the expected accuracy of these types of algorithms [24][25]. According to full-wave simulations this antenna provides a radiation efficiency of 91% with a beam efficiency of 52% at 60 GHz. As intended the gain is higher than the required 30 dBi within the complete operating band. It is also worth mentioning that the TA does not affect the return loss of the horn. The S_{11} of the complete antenna (Horn+Lens) is always below -15 dB in the entire band of operation. In TABLE 1 the developed TA is compared with other recent designs. Different types of lenses are considered: full dielectric TA manufacture with FDM 3D-printing (3D FDM TA); a TA of stacked metallic layers embedded in a dielectric host medium (Metallic TA); and a Fresnel Zone Plate Lens (FZPL). We conclude that the proposed solution provides a good balance between F/D , gain (G_{FF}) and 1 dB bandwidth (1 dB BW) with simple design and manufacturing processes.

V. CONCLUSIONS

The paper introduces GENERAL design rules for controlling the operation bandwidth of TA antennas, to overcome the limitation of aperture phase-wrapping associated limitations. In known designs, the F/D ratio is defined using heuristic assumptions. Herein, a closed form expression is presented to find the optimal F/D ratio of the antenna according to gain and bandwidth criteria. A horn antenna for the V-band was also designed for this specific application. The antenna design privileges a simple, low-cost fabrication process based on the most affordable 3D printing techniques, making it a cost-effective alternative to existing solutions for mm-wave high-gain antennas. The presented antenna example is intended for 5G backhaul communication links at WiGiG band.
