### **ABSTRACT**

Drought is considered the more harmful abiotic stress resulting in crops yield loss. Legumes in symbiosis with rhizobia are able to fix atmospheric nitrogen. Biological nitrogen fixation (SNF) is a very sensitive process to drought and limits legumes agricultural productivity. Several factors are known to regulate SNF including oxygen availability to bacteroids, carbon and nitrogen metabolisms; but the signalling pathways leading to SNF inhibition are largely unknown. In this work, we have performed a proteomic approach of pea plants grown in split-root-system where one half of the root was well-irrigated and the other was subjected to drought. Water stress locally provoked nodule water potential decrease that led to SNF local inhibition. The proteomic approach revealed 11 and 7 nodule proteins regulated by drought encoded by *P. sativum* and *R. leguminosarum* genomes respectively. Among these 18 proteins, three proteins related to flavonoid metabolism, two to sulphur metabolism and three RNA-binding proteins were identified. These proteins could be molecular targets for future studies focused on the improvement of legumes tolerance to

1  
2  
3 35 drought. Moreover, this work also provides new hints for the deciphering of SNF regulation  
4 36 machinery in nodules.

### 18 **INTRODUCTION**

19  
20 45 Abiotic stresses provoke the major losses in agricultural output. Among them, drought  
21 46 is considered to be the one that causes the most important crops yield loss (Boyer, 1982;  
22 47 Mittler and Blumwald, 2010). Moreover, global warming associated with climate changes  
23 48 will substantially increase drought conditions in the next 25 years. In fact, United Nations  
24 49 estimate that in 2025 1.8 billion people will be living in countries or regions with absolute  
25 50 water scarcity and two-thirds of the world population could be under conditions of water  
26 51 stress (FAO, 2007).  
27  
28  
29  
30

31 52 Legumes, mainly because of the high protein content of their grains, are some of the  
32 53 most important crops worldwide. Legumes have the ability to feed from atmospheric N<sub>2</sub>,  
33 54 through symbiosis with soil bacteria that gives rise to the development of a new organ, the  
34 55 nodule, where the nitrogen fixation process (SNF) is set up (Oldroyd *et al.*, 2011).  
35 56 Nitrogenase enzyme complex (Nase) within the bacteroids is the ultimate responsible of  
36 57 reducing the N<sub>2</sub> to ammonia. SNF is a highly-energy demanding process that involves  
37 58 significant respiration rates in the nodules, which must be finely-regulated because of the high  
38 59 susceptibility to oxygen of Nase (Oldroyd *et al.*, 2011). Indeed, SNF is an extremely sensitive  
39 60 process to environmental fluctuations, being the carbon burden and the need for extremely  
40 61 low-oxygen levels key aspects contributing to the high sensitivity of the process (Arrese-Igor  
41 62 *et al.*, 2011). In these context, three main regulatory mechanisms have been explored in the  
42 63 last decades: 1) regulation through the carbon flux within nodules, through a rapid nodule  
43 64 sucrose synthase (SS) down-regulation (González *et al.*, 1995); 2) nitrogen feed-back  
44 65 regulation (Serraj *et al.*, 2001) and 3) a regulation based on an interaction between the internal  
45 66 nodule oxygen concentration and reactive oxygen species (ROS) homeostasis (Diaz del  
46 67 Castillo and Layzell., 1995; Naya *et al.*, 2007). However, it is still a matter of debate which of  
47 68 these (C, O or N) is responsible of SNF regulation or whether they act in a co-operative way.

1  
2  
3 69 To improve symbiotically grown legumes tolerance to drought, a more precise  
4 70 understanding of the factors limiting and regulating the response of SNF under abiotic stresses  
5 71 is needed to find new potential molecular targets to modify or select. In this sense, “omics”  
6 72 represent an enormous powerful tool to find targets in complex mixtures of biological samples  
7 73 such as a whole-protein extract of a legume-nodule where the cohabitation of rhizobial  
8 74 bacteroids and plant cells takes place. Many proteomic studies have been performed to study  
9 75 legumes biology; however, the majority of them have been performed in non-symbiotic  
10 76 legumes (fed with external N). The proteomic studies of mature nitrogen-fixing nodules are  
11 77 scarce and mainly in the model plant *Medicago truncatula* (Bestel-Corre *et al.*, 2002; Oger *et*  
12 78 *al.*, 2012). Similarly, many proteomic approaches have been done in plant subjected to  
13 79 abiotic stresses, including drought (Roy *et al.*, 2011), but again the study of nitrogen-fixing  
14 80 legumes under these conditions is mainly focused in *M. truncatula* (Larrainzar *et al.*, 2007;  
15 81 Larrainzar *et al.*, 2009). Proteomics approaches in nodules of economically important  
16 82 legumes leading with abiotic stresses or drought is extremely limited and to our knowledge is  
17 83 restricted to soybean under drought (Gil-Quintana *et al.*, 2013).

18 84 In the last few years, the local or systemic origin of nitrogen fixation control under  
19 85 abiotic stresses have been addressed by the use of split-root system approaches for different  
20 86 legume species and stresses. For instance, *M. truncatula* (Gil-Quintana *et al.*, 2013a), soybean  
21 87 (Quintana *et al.*, 2013b) and pea (Marino *et al.*, 2007) under drought and *M. truncatula*  
22 88 exposed to Cd (Marino *et al.* 2013). In these works, the alteration of nodule metabolic  
23 89 pathways under drought has been shown to be mainly locally affected. Similarly, it has been  
24 90 shown that the alteration of ROS homeostasis, associated to nodule response to abiotic  
25 91 stresses, seems to be locally regulated. However, the signalling cascades leading to SNF  
26 92 inhibition are still in its infancy. Thus, in this work, we have performed a comparative  
27 93 proteomic approach of nodules from pea plants grown in split-root system (SRS) where half  
28 94 of the root system of pea plants was irrigated at field capacity, while the other half was water  
29 95 deprived to try to get further knowledge on the molecular control of SNF regulation under  
30 96 drought. The identification of new potential actors related to nodule functionality might be  
31 97 useful to further select plant genotypes with an increased tolerance to drought.

32 98

## 33 99 **MATERIALS AND METHODS**

### 34 100 *Experimental procedures and growth conditions*

35 101 Pea seeds (*Pisum sativum* L. cv. Sugar-lace provided by Bonduelle SA, Milagro,  
36 102 Spain) were sterilised and grown as described in Marino *et al.*, (20007). Four week-old plants

3 103 were irrigating to field capacity to one root-side (C) and withholding water/nutrients the other  
4 104 root-side (D) during seven days. Nodules were harvested, immediately frozen in liquid  
5 105 nitrogen and stored at  $-80^{\circ}\text{C}$  for analytical determinations.  
6  
7  
8 106

9  
10 107 *Water relations*

11 108 Nodule water potential was determined by a psychrometer Wescor HR-33T (Wescor  
12 109 Inc. 5500, Logan, UT, USA). Four nodules per split-root were collected and confined in C52  
13 110 sample chambers for at least 1 h until temperature and vapour equilibration was reached.

14  
15 111 Water content (WC) was calculated with the following formula.  $\text{WC} = (\text{FW}-\text{DW})/\text{FW}$ ,  
16 112 where FW and DW mean fresh weight and dry weight respectively.  
17  
18 113

19  
20  
21 114 *Nitrogen fixation determination*

22 115 NF was measured as apparent Nase activity, determining hydrogen evolution as  
23 116 described in Zabalza et al., (2008).  
24  
25 117

26  
27  
28 118 *N content determination*

29 119 Total root N content was determined with a NC 2500 Elemental Analyzer (Carlo Erba,  
30 120 Milan, Italy). Briefly, two to three milligrams of powdered plant material from each sample  
31 121 was separately packed in tin capsules. N content was determined by flash combustion at  
32 122  $1020^{\circ}\text{C}$ . The resulting combustion gases pass through a reduction furnace into the  
33 123 chromatographic column using helium as carrier gas and detected by thermal conductivity.  
34 124 Acetanilide was used as internal standard.  
35  
36 125

37  
38  
39 126 *Protein extraction*

40 127 Nodules ( $\sim 0,3$  g) were homogenised in a mortar and pestle with 1,2 mL of lysis buffer  
41 128 as described in Farinha et al. (2011). Protein content was assayed by the Bradford method  
42 129 (Bradford et al. 1976).  
43  
44 130

45 131 For the determination of the protein content from the plant and the bacteroidal  
46 132 fractions separately, fresh nodules were homogenised with lysis buffer (Farinha et al., 2011)  
47 133 and centrifugated at low-speed 2000 g to avoid bacterial disruption. The supernatant was kept  
48 134 for plant-fraction protein determination. The centrifugation pellet was washed three times  
49 135 with lysis buffer and boiled during 10 min with KOH 2M. It was centrifuged again and the  
50 136 protein content of the supernatant quantified by the Bradford assay (Bradford et al. 1976).

9 141

10  
11 142 *2D Electrophoresis*

12  
13 143       Samples containing 0.9 mg of protein, which corresponds 100-150 mg of nodules,  
14 144 were analysed as previously described (Farinha *et al.*, 2011; Valdes *et al.*, 2013) For each  
15 145 biological nodule sample, two biological replicates and three experimental replicates were  
16 146 performed (in Supporting Figure S2 are shown the 12 master gels performed). The first  
17 147 dimension was run onto pH 4-7, 18 cm immobilized pH gradient (IPG) strips (Immobiline  
18 148 DryStrips, GE Healthcare). For the second dimension, the strips were loaded on SDS-PAGE  
19 149 12 % polyacrylamide gels (26x20x0.1cm).

21  
22  
23

24 150

25  
26 151 *Image and data analysis*

27  
28 152       2-DE gels were analysed as described in Irar *et al.* (2010) by the use of the  
29 153 ImageMaster™ 2-D Platinum 5.0 Software (GE Healthcare). In order to compare the nodules  
30 154 proteome of the different samples, automatic spot matching was established between synthetic  
31 155 gel images. Careful visual inspection was performed to confirm correct spot matching.  
32  
33  
34

35 156

36 157 *Statistical analyses*

37  
38 158       The statistical evaluation of proteins expression differences among treatments was  
39 159 performed as previously described (Jorri n-Novo, 2009; Farinha *et al.*, 2011). Spots showing a  
40 160 quantitative variation or their relative spot volume ( $\geq$  Ratio 1.5) and positive GAP (Statistical  
41 161 parameters ImageMaster™ 2-D Platinum 5.0 Software) were selected as differentially  
42 162 expressed. Significant protein abundance was validated by Student's t-Test ( $p < 0.05$ ).  
43  
44  
45

46 163

47  
48 164 *Protein identification*

49 165       Proteins were identified at the Proteomics Platform of Barcelona Science Park,  
50 166 University of Barcelona (a member of ProteoRed network) by MALDI-TOF/TOF (4700  
51 167 Proteomics Analyzer, Applied Biosystems) or LC-ESI-QTOF (Q-TOF Global, Micromass-  
52 168 Waters) mass spectrometers as previously described (Irar *et al.*, 2010). The obtained results  
53 169 were submitted for database searching in a MASCOT search engine against non-redundant  
54 170 NCBI and Swissprot databases. The search parameters were: Oxidation of methionine

## 11 176 **RESULTS AND DISCUSSION**

### 12 177 *Drought effects on nodules of pea plants in split-root*

13 178 Environmental stresses induce a rapid inhibition of SNF process in legume nodules.  
14 179 Several works in the last few years have dealt with the question whether this inhibition is  
15 180 driven at the nodule level (local) or by a signal of shoot origin (systemic). In this sense, local  
16 181 SNF control under water stress has been shown in *M. truncatula* (Gil-Quintana *et al.*, 2013a),  
17 182 pea (Marino *et al.*, 2007) and soybean (Gil-Quintana *et al.*, 2013b). The local control of SNF  
18 183 under Cd has also been recently reported in *M. truncatula* (Marino *et al.* 2013). In pea, SNF  
19 184 control was shown to be related with a rapid down-regulation of SS, enzyme that hydrolyses  
20 185 the sucrose coming from the photosynthesis to ultimately feed the bacteroids mainly with  
21 186 malate for its energy obtaining (Gálvez *et al.*, 2005). This SS inhibition was associated to a  
22 187 cell redox imbalance (Marino *et al.*, 2007). However, the nodule metabolic adjustment  
23 188 leading to SNF inhibition seems to be species specific since for instance in *M. truncatula*  
24 189 subjected to Cd the local SNF control was also associated to changes in cell redox  
25 190 homeostasis but not to SS inhibition, as it has been also reported under drought (Naya *et al.*,  
26 191 2007). Indeed, SNF inhibition in *M. truncatula* under Cd was associated to a control  
27 192 involving leghemoglobin-O<sub>2</sub>-ROS-Nase. Thus, nodulated pea plants were grown in an SRS  
28 193 and subjected one part of the split-root to water deprivation whereas the other half root was  
29 194 maintained in optimal conditions. In agreement with previous results (Marino *et al.*, 2007), in  
30 195 this study, the SRS allowed having in the root system of the same plant, nodules with a  
31 196 reduced water potential (-1,1 MPa) in the droughted-half whilst the nodules of the control-half  
32 197 had a water potential typical of well-irrigated plants, around -0.6 MPa (Fig. 2A). Nodule  
33 198 biomass in the droughted half root ( $11.54 \pm 1.15$  mg of nodules dry weight) was reduced  
34 199 respect to the control half root ( $18,46 \pm 1.92$  mg of nodules dry weight). This difference was  
35 200 due to a growth arrest of the nodules, since nodule water content was similar among control  
36 201 ( $87,1 \pm 1,2$  %) and stressed nodules ( $86,0 \pm 0,2$  %) what indicates the still mild degree of the  
37 202 imposed water stress. We checked that SNF was actually inhibited in the droughted-half and  
38 203 we confirmed a reduction close to the 50% in Nase activity (Fig. 3). According to the mild

1  
2  
3 204 water stress, although SNF was inhibited, roots total N content did not still change between  
4 205 the control and the treated halves (data not shown).

5  
6 206 SS and Nase are among the most sensitive nodule metabolism components to  
7  
8 207 environmental stresses in the plant and bacteroid respectively (Arrese-Igor et al., 2011). We  
9  
10 208 performed a western blot for these two components and we observed that both SS and Nase  
11 209 (NifD) were reduced in the droughted half of the root, with their content representing 38 and  
12 210 85% of control nodules respectively (Fig. 2C). However, the degree of this 7-day water  
13 211 deprivation stress was moderate since total protein content of both the plant fraction and the  
14 212 bacteroids did not vary between both halves of the root (Fig. 2B). Moreover, the stronger  
15 213 drought effect observed on SS compared to NifD suggests, together with the overall down-  
16 214 regulation of the identified plant proteins compared to the rather up-regulation of bacteroidal  
17 215 proteins (see below), that drought is perceived first in the nodule plant fraction, as it has been  
18 216 already shown in grain legumes under abiotic stresses (Arrese-Igor et al., 2011).

19 217

20 218 *Proteome analysis of nodules under two water regimes within the same plant*

21 219 To further understand the SNF regulation we sought for new actors involved in nodule  
22 220 response under drought by performing a comparative proteomic study among nodules of both  
23 221 sides (control and drought) of the splitted-root of pea plants. To estimate the changes in  
24 222 protein abundance between the two nodule proteomes, we used normalized spot volume or  
25 223 volume percentage (individual spot volume / all spots within a given gel) using the  
26 224 ImageMaster software. The pattern of spot distribution was similar between the 2DE-gels  
27 225 along the separation range *pI* 4-7 and molecular mass 14-66 KDa (Fig. 4A). However, the  
28 226 number of spots was different between control and water-stressed nodules, 1056 and 1179  
29 227 spots respectively (Fig. 4). When comparing the proteome of control nodules versus nodules  
30 228 under drought, the percentage of spot matching was 81% (906 spots; Fig. 4B). Moreover, we  
31 229 looked for spots with fold-change ratios  $\geq 1.5$  ( $p < 0.05$ ) between control and drought nodule  
32 230 proteomes (Fig. 4). About 2.3% of the proteins (21 spots) shared by the control and the water-  
33 231 stress treatments registered significant differences in accumulation. In order to determine the  
34 232 variation among nodule proteins the linear relationship between CV and normalized spot  
35 233 volumes was calculated. The correlation (Student's t-test,  $p < 0.01$ ) between technical  
36 234 replicates was of 0.97 and 0.98 for control and drought treatments respectively, while between  
37 235 biological replicates was somewhat lower, 0.83 and 0.86 for control and drought treatments  
38 236 respectively (Table 1). The scatter plots generated by the Image Master 2D Platinum 5.0  
39 237 software is provided in Supporting Figure S1. Regarding biological replicates, the correlation

238 between the less abundant proteins was higher than that observed among high abundant  
239 proteins (Supporting Fig. 1). Besides, the average CV was lower between technical replicates  
240 (0.20-0.22) when compared with biological replicates (0.34-0.39) (Table 1).

241 The analysis of the 2-DE gel images representing the nodule proteome of the two  
242 halves of the split-root, revealed 21 protein spots with quantitative differences in their  
243 accumulation (Fig. 4). Out of these, eighteen were identified by MS/MS, eleven encoded by  
244 the *P. sativum* genome (P1-11, Table 2) and seven by *R. leguminosarum* (B1-7, Table 3). Five  
245 out of the 18 identified spots (P7, B1, B2, B3 and B4) were significantly accumulated in the  
246 drought treatment and thirteen (P1, P2, P3, P4, P5, P6, P8, P9, P10, P11, B5, B6 and B7) in  
247 the control treatment. Interestingly, while there was a general down-regulation of plant  
248 proteins, four out of the seven bacteroidal proteins identified were up-regulated. This pattern  
249 has been previously observed in *M. truncatula* root nodules under drought suggesting a  
250 different adaptative mechanism to drought of both symbionts (Larrainzar et al., 2007).

#### 251 252 *Identified plant proteins were mainly down-regulated by drought*

253 This comparative proteomic approach allowed identifying, both in the plant fraction  
254 and in bacteroids, proteins regulated by drought related to sulfur (S) metabolism, specifically  
255 components of the S assimilation pathway involved in methionine metabolism (Supporting  
256 Table S2; Fig. 5; Tables 2, 3). S is one of the six macronutrients necessary for plant growth, in  
257 particular is required for cysteine and methionine synthesis together with a variety of  
258 secondary metabolites. Plants, in contrast to animals, are able to assimilate S from the  
259 inorganic S present in the soil. Sulfate is first incorporated into cysteine for the posterior  
260 synthesis of other S-containing compounds. S assimilation pathway appears to be connected  
261 with drought stress response, not only for the production of the well-known sulfur containing  
262 glutathione and choline-O-sulfate but, for instance, it has been shown that some abscisic acid  
263 functions are sulfate-dependent (Ernst *et al.*, 2010). Overall, it has been suggested that S  
264 assimilation must be tightly regulated under this stress so the plant can cope with “competing  
265 interests” between the different metabolic pathways important for plant survival under  
266 drought (Chan *et al.*, 2013). Methionine adenosyltransferase (S-adenosylmethionine  
267 synthetase 2; EC 2.5.1.6; spot P2, Fig. 4, Table 2) which is in charge of the synthesis of S-  
268 adenosyl-L-Met (SAM), a primary methyl-group donor and a precursor of important  
269 metabolites as polyamines, or ethylene (Amir *et al.*, 2002), has been found to be down-  
270 regulated by drought in the nodule plant partner (Fig. 5A). In the bacterial partner, the S-  
271 adenosyl-L-homocysteine hydrolase enzyme (EC 3.3.1.1; spot B2, Fig. 4, Table 3),

1  
2  
3 272 responsible for the reversible conversion of S-adenosyl-L-homocysteine into adenosine and  
4 273 homocysteine increased *ca.* 4 times in response to drought (Fig. 5B). We might speculate that  
5 274 the response of these two enzymes could provoke a decrease in SAM content in response to  
6 275 drought. Interestingly, in a proteomic study of *M. truncatula* nodules subjected to drought  
7 276 only five proteins were identified showing a significant down-regulation during drought stress  
8 277 (Larrarinzar *et al.*, 2007). Out of those five proteins, Methionine synthase was the one  
9 278 showing the strongest response. S-adenosylmethionine synthetase and Methionine synthase  
10 279 down-regulation have also been found associated with nodule ageing (Matamoros *et al.*,  
11 280 2013). Both in nodule natural senescence and in stressed-induced senescence ROS over-  
12 281 production has been reported (Marino *et al.*, 2009). In a proteomic approach during *M.*  
13 282 *truncatula S-meliloti* symbiosis, both plant and microsymbiont S-adenosylmethionine  
14 283 synthetase was found sulfenylated in mature nodules (Oger *et al.*, 2012). Overall, ROS  
15 284 produced in nodules could be involved in S-metabolism regulation. Finally, it has been shown  
16 285 that SNF in *Trifolium repens* was drastically reduced in S-deficient plants in relation, among  
17 286 others, with Nodule O<sub>2</sub> and Nase (Varin *et al.*, 2010)

18 287 Three out of the eleven proteins identified from the host plant belong to the flavonoid  
19 288 biosynthesis pathway. Two chalcone flavonone isomerases (spots P6 and P8; Fig. 4, Table 2)  
20 289 and the Caffeoyl-CoA O-Methyltransferase enzyme (spot P4; Fig. 4, Table 2). Chalcone  
21 290 flavones isomerases catalyze the conversion of chalcone into a flavonone in different steps of  
22 291 flavonoid biosynthesis. The Caffeoyl-CoA O-Methyltransferase (CCoACOMT) converts  
23 292 caffeoyl-CoA into feruloyl-coA. Interestingly, coupled to this reaction SAM is transformed  
24 293 into S-adenosyl-L-homocysteine. As stated above, SAM production is surely impaired  
25 294 because of the S-adenosylmethionine synthetase down-regulation which would secondarily  
26 295 limit the substrate availability for CCoACOMT proper functioning. CCoACOMT function  
27 296 has been mainly associated to lignin biosynthesis (Guo *et al.*, 2001). In the *M. truncatula cral*  
28 297 mutant showing compact root architecture, CCoACOMT was the most down-regulated gene  
29 298 and this mutant presented reduced lignin content and changes in flavonoid pattern. *cral*  
30 299 mutant did not present any morphological nodule phenotype, although its functionality was  
31 300 not investigated (Laffont *et al.*, 2010). In tissues other than nodules CCoACOMT has  
32 301 generally been found to be induced upon abiotic stresses for example in soybean roots  
33 302 (Yamaguchi *et al.*, 2010), sunflower seeds (Fulda *et al.*, 2011) or in rice leaves (Salekdeh *et*  
34 303 *al.*, 2002). Overall, it seems that CCoACOMT has a nodule specific regulation and that in  
35 304 lignifications processes might be related to plant response upon environmental changes.

1  
2  
3 305 Besides, in the plant partner, 3 glycine-rich proteins (GRPs) were also down-  
4 306 accumulated under drought stress (Fig. 5A). These three GRPs belong to the Class IV of  
5 307 GRPs also known as RNA-binding GRPs (GR-RBP-s) because besides the glycine-rich  
6 308 domain, they present a RNA-recognition motif (RRM) (Lorkovic *et al.*, 2010). GRPs have  
7 309 been associated to a wide range of different functions in plant cells including cell wall  
8 310 structure, plant defence, cell elongation, abiotic stress response or plant flowering and  
9 311 development (Mangeon *et al.*, 2010). It has been determined that the expression of GRPs is  
10 312 regulated by a number of external stimuli including drought (Sachetto-Martins *et al.*, 2000).  
11 313 The *Arabidopsis thaliana* genome encodes eight GR-RBPs. The GRP corresponding to the  
12 314 spot P11 (Fig. 4; Table 2), shows an 84% of identity with *Arabidopsis* GRP7. Interestingly  
13 315 GRP7 was found to be repressed by ABA and osmotic stress (Cao *et al.*, 2006). One of the  
14 316 functions that have been attributed to AtGRP7 is the regulation of stomata opening and  
15 317 closure under stress conditions (Kim *et al.*, 2008). However, the mechanisms of how GR-  
16 318 RBPs contribute to plant responses under stresses are largely unknown. Moreover, RBPs are  
17 319 also known to regulate gene expression in different ways including alternative splicing. A  
18 320 substantial fraction (similar to 30%) of plant genes is alternatively spliced, and many plant  
19 321 genes undergo alternative splicing in response to a variety of stresses and might be important  
20 322 for stress adaptation (Reddy *et al.*, 2007). In this context, the GRP-target RNA interactions  
21 323 and the GRP-mediated regulation of RNA metabolism and folding in post-transcriptional gene  
22 324 regulation are not fully understood but could be essential for nodule, and plants in general,  
23 325 response to abiotic stresses.

24 326 We also identified a GroEL-like chaperone ATPase, a proteasome subunit and the 12-  
25 327 oxophytodienoic acid 10,11-reductase were also identified in the plant fraction and were  
26 328 down-regulated by drought stress (Fig. 4, 5A; Table 2). The 12-oxophytodienoic acid 10,11-  
27 329 reductase (EC 1.3.1.42) is an enzyme of the jasmonic acid biosynthesis pathway. Jasmonates  
28 330 are ubiquitous stress-signalling compounds of plants, finding this enzyme down-regulated  
29 331 could mean that although the 7-day drought stress treatment was slight to provoke nitrogen  
30 332 fixation inhibition without generating a general plant breakdown but it was strong enough to  
31 333 induce a down-regulation of JA pathway.

32 334 Among all the differentially expressed proteins encoded by the pea genome only one  
33 335 of them was induced by drought (Figure 5A, spot P7). The nodule lectin PsNLEC-1 whose  
34 336 content doubled in the nodules subjected to drought. Lectins are nonenzymatic carbohydrate-  
35 337 binding proteins that specifically recognize diverse sugar structures and mediate a variety of  
36 338 biological processes, including signalling cascades, cell to cell communication, molecules

1  
2  
3 339 transport or enzymes posttranslational regulation (Kijne *et al.*, 1997.). Legume lectins  
4 340 function associated to the nitrogen fixing-process is still unclear but they are thought to have a  
5 341 role in promoting the aggregation of rhizobia in infectable root hairs (Diaz *et al.*, 1995), in  
6 342 stimulating mitotic activity in root cortical cells (Brewin and Karakailsky, 1997) and in the  
7 343 infected zone as a transient N reserve (Law, 1996). PsNLEC-1 has been shown to be  
8 344 localized in the symbiosome compartment of infected cells and in the vacuole (Dahiya *et al.*,  
9 345 1997), and it has been suggested that it might play a role in nodule development (Dahiya *et al.*,  
10 346 1998; Bolaños *et al.*, 2001). Plant lectins have also been proposed to play a role in abiotic  
11 347 stresses response (Jiang *et al.*, 2010, Babosha, 2008). For instance in Arabidopsis 89 genes  
12 348 out of 199 lectin genes were regulated by different abiotic stresses, and 62 out of this 89 were  
13 349 regulated by drought (Jiang *et al.*, 2010). The functional role of lectins under abiotic stresses  
14 350 is unclear and much remains to be learned about their function but it seems that they might be  
15 351 acting in the signalling cascades downstream the stress perception (Jiang *et al.*, 2010).  
16 352 Interestingly, the pea lectin receptor PsLecRLK was induced upon salt and drought exposure,  
17 353 further evidencing a potential role of lectins in pea signal transduction in response to drought  
18 354 (Joshi *et al.*, 2010). Moreover, it has been suggested that lectins could be playing a role in the  
19 355 protection of cells against oxidative stress (Babosha *et al.*, 2008), which has been already  
20 356 been shown to occur in pea nodules under drought (Marino *et al.*, 2007).

33 357

34 358 *Microsymbiont proteome response to drought*

35 359 From bacterial origin we identified seven proteins differentially expressed, three  
36 360 down-regulated and four up-regulated (Fig. 5B). Malate dehydrogenase (MDH) content  
37 361 slightly increases in bacteroids in response to drought. Sucrose is the main carbohydrate  
38 362 provided by the plant to the nodules, sucrose is then hydrolysed to dicarboxylic acids to  
39 363 provide with carbon and energy to the bacteroids. In this work, SS content is reduced by water  
40 364 stress (Fig. 2C) and it has been previously shown that SS inhibition leads to nodule malate  
41 365 content depletion (Marino *et al.*, 2006, Marino *et al.* 2007). Thus, we could speculate that an  
42 366 early response to malate limitation could be MDH induction in the bacteroids. In bacteroids of  
43 367 common bean nodules MDH was also shown to be induced upon mild salt stress which also  
44 368 provoked malate content diminution in the nodules; however, a more severe stress inhibited  
45 369 MDH activity (Ferri *et al.*, 2000).  
46  
47  
48  
49  
50  
51  
52  
53

54 370 Inosine-5'-monophosphate (IMP) dehydrogenase (EC 1.1.1.205) content in the  
55 371 microsymbiont was doubled upon drought exposure. This enzyme catalyzes the NAD<sup>+</sup>  
56 372 dependent conversion of IMP to Xanthine monophosphate in the purine metabolism pathway.  
57  
58  
59  
60

1  
2  
3 373 There is not much evidence of the potential role of this enzyme under stress conditions. IMP  
4 374 dehydrogenase induction could be related to NADH regeneration of great importance to  
5 375 support antioxidative machinery in stress conditions and also to store nitrogen in the form of  
6 376 purines which is not being exported from the nodule due to water stress.

7  
8  
9 377 Although plants mainly supply carbon skeletons to bacteroids, and in return they  
10 378 receive ammonia the metabolic exchange is more complex. In fact, effective N<sub>2</sub> fixation by *R.*  
11 379 *leguminosarum* bv *viciae* bacteroids requires either one of two broad-specificity amino acid  
12 380 ABC transporters (AAP and BRA) (Lodwig et al., 2003). This phenomenon is named  
13 381 symbiotic auxotrophy because bacteroids become dependent of amino acids supply from the  
14 382 plant (Prell et al., 2009). Preventing branched-chain amino acid uptake by nodule bacteria  
15 383 leads to amino acid starvation, failure to fully develop, reduced size, and endoreduplication of  
16 384 chromosomes and provokes a nitrogen starvation phenotype when inoculated on pea (*Pisum*  
17 385 *sativum*) plants (Lodwig et al., 2003). In the present work, we have found a component of the  
18 386 ABC transporter AAP, the General L-amino acid-binding periplasmic AAPJ protein (spot B4;  
19 387 Fig. 4, Table 3). This component was induced in pea nodules in response to drought. The role  
20 388 of these transporters in relation to abiotic stresses remains to be elucidated. However, Taté et  
21 389 al., (2012) suggested a putative role of glutathione in the regulation of amino-acid cycling in  
22 390 bacteroids. Thus the reduction in glutathione content in nodules subjected to drought (Marino  
23 391 et al., 2007) might be linked to the induction of the AAPJ protein in this work.

24 392 Among the three down-regulated proteins, NifH, the Fe-component the Nase complex,  
25 393 was identified (spot B5; Fig. 4; Table 3). This is in agreement with the western blot showing  
26 394 NifD, the MoFe-component of Nase, down-regulation in the droughted half-root (Fig. 2C).  
27 395 The high sensitivity of Nase under environmental stresses has been previously reported,  
28 396 among others, in *M. truncatula* under Cd (Marino et al., 2013) and *M. sativa* under drought  
29 397 (Naya et al., 2007). Besides the biological relevance of NifH down-regulation, it represents  
30 398 also a very good internal control of the validity of the proteomic assay. The other two down-  
31 399 regulated proteins identified in *R. leguminosarum* bacteroids were an ATPase and a  
32 400 thioredoxin family protein (Fig. 4, Table 3). ATPase down-regulation could reflect the  
33 401 reduction in bacteroid respiration related to carbon limitation due to SS down-regulation (Fig.  
34 402 2C). Thioredoxins family is composed by thioredoxins but also by glutaredoxins and  
35 403 peroxiredoxins. They are small redox proteins that play a role in redox signaling and they are  
36 404 associated to a wide range of cellular processes. In legume bacteroids, these proteins have  
37 405 been shown to be required for optimal nodule development and nitrogen fixation activity  
38 406 (Frendo et al., 2013)

1  
2  
3 407 In conclusion, the identification of 11 *P. sativum* and 7 *R. leguminosarum* proteins  
4 408 regulated by drought in nodules of pea plants grown in split-root provides new potential  
5 409 targets for future studies focused on legumes drought tolerance improvement. Moreover, the  
6 410 overall down-regulation of the identified plant proteins compared to the rather up-regulation  
7 411 of bacteroidal proteins suggests an enhanced sensitivity of the nodule plant fraction to the  
8 412 stress. Finally, this study highlights the importance of S-metabolism in water stress conditions  
9 413 and to our knowledge provides the first hints of GR-RBPs potential role in legume nodule  
10 414 responses under stress conditions and opens a new avenue for the implication of post-  
11 415 transcriptional gene regulation in nitrogen fixation regulation.

## 27 590 SUPPORTING INFORMATION

28  
29 591 **Figure S1.** Linear regression of protein amounts between 2-DE gel replicates from the control  
30 592 and droughted halves of the pea split-root system. The linear relationship between spot  
31 593 normalized volumes (% Vol.) is shown for triplicate gels running three biological replicates.

32  
33  
34 594 **Figure S2.** 2D master gels from nodules of control (C) and droughted (D) halves of the split-  
35 595 root system.

36  
37 596 **Table S1.** Identification of plant and bacteroid proteins.

38  
39 597 **Table S2.** Quantification data for the identified protein spots.  
40  
41

42 598

## 43 599 TABLE LEGENDS

44 600 **Table 1.** Comparison of the analytical and biological variation across *P. sativum* nodules  
45 601 separated by 2-DE. Average values of coefficient of correlation (r) and coefficient of variation  
46 602 (CV) obtained from pairwise comparison between normalised protein spot volumes across  
47 603 distinct gel replicates are shown (two independent protein extractions were performed and 2-  
48 604 DE gels were run in triplicate).

49  
50  
51 605 **Table 2.** Summary of the *P. sativum* nodule plant fractions differentially regulated proteins in  
52 606 response to drought.

53  
54  
55 607 **Table 3.** Summary of the *P. sativum* nodule bacteroids differentially regulated proteins in  
56 608 response to drought.

609

610 **FIGURE LEGENDS**

611 **Figure 1.** *P. sativum* plants grown in split-root-system leading to a root system divided in two  
612 equal parts.

613 **Figure 2.** A) Nodule water potential in control and water stressed *P. sativum* plants grown in  
614 split-root system. B) Nodule plant-fraction and bacteroidal protein content and C) protein  
615 content of sucrose synthase (SS) and a nitrogenase component (NifD) of control and water  
616 stressed nodules of *P. sativum* plants grown in split-root system. Each bar represents mean  $\pm$   
617 SE for n=6. Asterisk (\*) represents significant differences ( $p \leq 0.05$ ).

618 **Figure 3.** A) Nitrogen fixation in control and water stressed nodules of *P. sativum* plants  
619 grown in split-root system. Each bar represents mean  $\pm$  SE for n=6 Asterisk (\*) represents  
620 significant differences ( $p \leq 0.05$ ).

621 **Figure 4:** Representative 2-DE gel images of *P. sativum* nodule proteome from the control  
622 (C) and droughted (D) halves of the split-root system revealed protein spots with quantitative  
623 differences in their accumulation. A) Comparison of total proteins of control and drought  
624 treatment. The selected spots are indicated in the gels. With arrows and in red are represented  
625 unidentified spots. B) Venn diagrams showing the mean number of matching spots between C  
626 (blue) and D (green) provenances after synthetic gel comparisons using the ImageMaster  
627 Platinum software.

628 **Figure 5.** Analyses of protein spots with significant differences between control and water  
629 stressed nodules of *P. sativum* plants grown in split-root system. A) Identified proteins from  
630 the nodule plant fraction B) Identified proteins from the nodule bacteroids. Quantitative  
631 variation of protein abundance was validated by Student's t-test ( $P < 0.05$ ). Data are shown as  
632 mean  $\pm$  SE of two biological replicates.

**Table 1.** Comparison of the analytical and biological variation across *P. sativum* nodules separated by 2-DE. Average values of coefficient of correlation ( $r$ ) and coefficient of variation (CV) obtained from pairwise comparison between normalised protein spot volumes across distinct gel replicates are shown (two independent protein extractions were performed and 2-DE gels were run in triplicate).

	Control	Drought
<b>Technical replicates</b>	CV = 0.20 $r = 0.97$	CV = 0.22 $r = 0.98$
<b>Biological replicates</b>	CV = 0.39 $r = 0.83$	CV = 0.34 $r = 0.86$
